Acknowledgements

I would like to acknowledge the contributions to this work of my thesis advisor, Professor Sharon Sickel; for her many ideas and criticisms, and her continual encouragement and support. I am grateful to the members of my committee, Professors Frank Deremer and Carl Morgenstern for their scrutinization and approval of various drafts. I would also like to thank John McCarthy, Lester Earnest and the Stanford Artificial Intelligence Laboratory for allowing me access to their facilities for the implementation of my research.

I am indebted to all of my friends and family, who never doubted that I would succeed, thus making it impossible for me to quit.

Finally, I would like to express my deep gratitude to the one person who really kept me going, my friend, colleague, and husband, John Allen, for his encouragement, patience, answers, and insights.

The work reported herein was supported in part by the Office of Naval Research under contract grant number ONRN0001478C0682.

Introduction

"Software is 5% of the USAF's budget, 6% of NASA's budget and is a 10 billion dollar a year industry (over 1% of the GNP)."

Standish [S 74]

"Of the estimated DOD software cost of \$2.5 billion previously identified, 38% was for analysis, 15% for coding, and 47% for validation according to the Air Force study. ARPA is spending annually \$3.5 million developing techniques to enable the computer itself to write and debug programs, given only a specification of the problem and the results desired."

Lukasik [L 79]

"The one invariant in the computer field - whether mainframe, mini, or micro - is increasing software costs. ...75 percent of the mainframe system dollar currently goes for software. ...Systems software typically represents 50 percent of the mini manufacturer's development budget (hardware costing 40 percent and services making up the remaining 10 percent). ...software costs tend to dominate in under-100-unit quantities - even on micros."

Davis [D 78b]

Software is expensive and too often bug ridden. "Debugging" is still the most commonly used method of increasing confidence in the correctness of a program. As indicated by the statistics above, validation of the correctness of programs is a difficult and expensive task. Many approaches have been proposed to ensure reliable programs, some dealing with the programming task and others with proving a completed program does what is intended. Verification techniques have been developed to prove that a program meets its specifications.

Several attempts have been made to provide automatic verification systems. Some of these systems are good at proving verification conditions for a specific problem domain, employing strategies that are geared to that domain; however, the ability to handle problems in a new subject domain typically requires extensive modifications of the system.

A much harder problem is discovery of the verification conditions to be proved. One must find assertions (statements of first order logic) that characterize the desired behavior of the program. It is difficult enough to read someone else's program and determine what is actually going on, let alone figure out what the programmer had intended to do. Even when verification is done by the original programmer, we are asking a lot. This person must be able (assuming a structured approach to the task) to move from logical assumptions about the problem domain (whether or not these are stated formally) to an implementation in a programming language, and then back again to the logical base as a source of assertions from which the verification conditions can be derived.

It is possible to generate some of these assertions automatically from the text of the program. Usually the programmer supplies the critical assertions on which his program was based, letting the machine fill in the necessary details. However, one might question the validity of this approach. A "proof of correctness" is really just a proof of equivalence of two specifications of the problem, one expressed in logic, the other in a programming language. If we derive the assertions (manually or automatically) from the program itself, then we lose the redundancy of the two specifications; i.e., we lose the basis of our confidence that the verification provides an indication of true correctness.

Furthermore, if verification fails, several explanations are possible. Perhaps the program is incorrect; perhaps the specifications are incorrect or incomplete; perhaps the verifier is incorrect or not sufficiently powerful to find a proof even though one does exist. If verification is successful, then again several explanations are possible. Perhaps we have a correct program; perhaps the verifier has made a mistake. Assuming that the verifier contains no bugs, we have a proof that the program meets its specifications, but the specifications may not be an accurate embodiment of what we had in mind.

Therefore several researchers, the author included, feel that a specification of the task should be written before a program is written to accomplish the task. The specification should be written in a high level language that enables one to describe what is to be accomplished, indicating functional relationships without having to consider computational details. Such a specification, in which only the abstract

description of the problem is required, is less prone to error than a typical programming language specification in which every detail of the computation must be provided. The problems of incomplete or incorrect specifications do not go away, however we claim they are more tractable with this approach.

Program synthesis is the generation of a computational specification of a problem or task from a descriptive specification. Again, we do not have the redundancy of two specifications, one descriptive and one computational, both written by the programmer, but we feel, as discussed above, that the descriptive specification is less prone to error. Several approaches to program synthesis are currently being investigated. We shall review them briefly here; more detail is given in the section on historical background.

The field of programming methodology has offered a great deal of assistance, pointing out ways to write a program. Most notable and generally accepted is Dijkstra's approach of "structured programming", also called "stepwise refinement" (Wirth), of the problem. Although intended as a discipline for humans to follow, it also provides guidelines that can be elaborated to direct programming by the computer itself, perhaps with human intervention.

Several investigators have taken a deductive approach to the stepwise refinement process. The computer is given specific rules by which it can rewrite statements syntactically while maintaining equivalent meaning. This kind of program synthesis is closely related to program transformation. The intent of a program transformation system is to make the given program more efficient while preserving its meaning. A

typical transformation is one that replaces recursion by iteration, although this does not always result in greater efficiency. In a synthesis system, a descriptive statement in a specification language is transformed into an operational statement in a programming language. The specification language may be a superset of the target programming language. The system successively refines a high level description into a lower level (computational) description.

Less formal techniques have also found favor. Natural language dialogues have been used to describe a problem to the computer. The user of this kind of system specifies the task at a general level, filling in the details as requested by the computer.

Still other approaches employ specification by example. Some systems synthesize programs from sample input-output pairs. For example, the pair

$$(a (b c) d) \Rightarrow (d (b c) a)$$

might indicate a procedure to reverse the elements in a list. It might also represent a procedure to switch the first and last elements of a list; thus, one must be sure to provide a sufficient set of examples to determine the desired function.

Another attempt at synthesis by example provides sample execution traces. For example, the sequence

$$(4 \ 14) \Rightarrow (2 \ 4) \Rightarrow (0 \ 2) \Rightarrow 2$$

might suggest the Euclidean algorithm for finding the greatest common divisor of two integers.

Each of the techniques mentioned above have been investigated as a means to synthesize programs in a specific target language. It is our thesis that the synthesis of

an algorithm is a target-language-independent process. We have implemented a system to generate programs from logic specifications. The system is "reasonably" target-language-independent, as will be explained later on. The specifications are first translated into an intermediate language and then a program is generated from the intermediate form. We drop the word "synthesis" and use program "generation" instead to avoid any misunderstanding of the claims being made. The specification language for this system includes a subset of first-order Predicate Calculus known as Horn Clauses. The specifications we require are "descriptive" in that they specify the logic of the program without specifying the control, but they are also, in part, "computational" in that the Horn clauses could be "run" as programs given a complete theorem prover, or logic interpreter.

The system was implemented in MACLISP on a DEC KL10 at the Stanford Artificial Intelligence Laboratory. In this dissertation we describe the implementation and prove that it provides a valid way to derive correct programs. This is accomplished by proving that the top level mappings from specification to intermediate language to target program (the proof is for the mapping to LISP) are correct; the entire implementation is not proved correct.

We begin by giving a brief history of the approaches taken by other investigators in this area, and then describe the system invented by the author. We formally describe the specification language via a context-free description of the syntax (see page 22) and an axiomatic specification of the semantics (see page 24). Motivation for requiring particular items in the specification is provided as well.

The relationship between a specification and a program written for a logic interpreter is explored in Chapter 4, page 28).

We then describe the intermediate language in detail, again supplying a context-free grammar for the syntax (see page 35), and the axiomatic semantics (see page 36).

The mapping from specification language to intermediate language is described by means of a function *I*, for *internalize*, and we prove that this mapping preserves the axiomatic semantics of the specifications.

We then describe the mapping from the intermediate language to LISP and prove that the semantics is again preserved by the translation.

In Chapter 10, we describe how to extend the system to handle generation of programs in more languages. The additions required for each new language are referred to as a "back end" for that language. The implementation of the "back end" for LISP and that for Pascal are also discussed.

We include some notes on the implementation and then discuss the conclusions that can be drawn from this effort, as well as topics of further research that were suggested by the project.

The appendices include several sample specifications and the programs generated from them, the specification of a program generation system, and the listing of the entire system along with the code that implements the "back end" for LISP and that for Pascal.

This system described is unique in its ability to generate programs in more than

one language. The recipe provided explains how to construct the additions required for any new language. Given the back-end describing a particular target language, we can synthesize the system itself in the language, making it immediately portable. More importantly, it provides a means of obtaining correct programs that is decidedly less painful than verification. The user is still required to specify the logic of a program, but the language used in the specification frees the user from concerns of representation and implementation.

The sobering fact remains that regardless of how (or when) we arrive at specifications for a program, we can have no guarantee of their correctness (in the sense that we have both a true and complete specification of the problem we had in mind), and any attempt at verification of a program is simply a proof of equivalence of program and specifications. We simply do the best we can to increase our confidence that our programs accomplish their intended purpose.

History

Computer scientists have always looked for ways to make the programming task easier and less prone to error. The natural way to accomplish this is by using the computer itself as much as possible to do its own coding. The theoretical foundation for automatic programming was established by Kleene [K 52] in the 1940's. Kleene proved that if the existence of a number satisfying certain properties can be proven in a formal intuitionist system,¹ then the definition of a function computing that number can be extracted from the proof. The first major attempt at automatic programming was the development of FORTRAN.

"If it were possible for the 704 to code problems for itself and produce as good programs as human coders (but without the errors), it was clear that large benefits could be achieved. ...The goal of the FORTRAN

¹An intuitionist system allows only constructive proofs. See [K 52].

project was to enable the programmer to specify a numerical procedure using a concise language like that of mathematics and obtain automatically from this specification an efficient 704 program to carry out the procedure."

Backus, et. al. [B 57]

In the 1960's several high level languages were introduced as means of specifying problems to the computer in a way more natural to us, letting the machine do the coding. Over the years, our concept of "automatic programming" has changed. We no longer consider a compiler an automatic program synthesizer.

J. R. Slagle [S 65] applied his question answering program "DEDUCOM" to the task of generating programs. The relation between input and output was expressed in predicate calculus. His technique was to prove a theorem and write a program by keeping track of the substitutions made for certain crucial variables in the course of the proof.

A similar approach was described by Waldinger [W 69]. He extended the technique allowing branches and loops to be written. Again, specifications for the program were described in Predicate Calculus as a relation between input and output variables. Mechanical theorem proving techniques were used to generate a constructive proof of the existence of output values satisfying the specifications. A program was then extracted from the proof.

Since 1970, several approaches to program synthesis have been investigated. The resolution theorem proving approach proved to be impractical, requiring too much space while considering all possibilities. Lee and Chang [LC 74] proposed to

overcome the memory saturation problem with an interactive system based on the concept of structured programming. Using the technique of stepwise refinement, a program was generated in terms of subprograms until each subprogram became an "atomic program", i.e. executable. At each step, some appropriate information would be selected by the user for the computer to use to generate a subprogram. In this way, the computer only had to handle a small amount of information.

Many researchers abandoned resolution methods entirely in favor of deductive systems with many rules of inference. Buchanan developed a system [B 74] based on the program verification formalism of Hoare [ILL 75]. Input to the system was given in "frames" composed of assertions, state descriptions, axioms and rules. A rule could be: a primitive procedure with preconditions and postconditions specified; a definition, stating the equivalence of two assertions; or an iterative rule specifying conditions that, if satisfied, would justify the assembly of a "while" loop to achieve the associated goal. The input specifications were rather complicated. An iterative rule involved specifying a name, a basis assertion, a loop invariant, an iteration step assertion, an iterative goal, a loop control test, and an output assertion (the last two could possibly be the same as the iterative goal). It was also possible to give advice to the system interactively, to guide the synthesis process. This system could automatically generate conditional statements as well.

Dershowitz and Manna [DM 75] discussed formalization of several programming techniques involved in structured programming, and demonstrated the use of these rules by hand-synthesizing programs. Manna and Waldinger [MW 77c]

have implemented such techniques in "DEDALUS", an experimental program synthesis system. They have attempted to make life easier for the user by simplifying the input required. They have not, as yet, attempted to describe completely their specification language; it is a superset of the target language containing quantifiers and several high-level constructs from the subject domain. Hundreds of transformation rules are available, embodying a great deal of knowledge about the domain for which programs are to be synthesized. The transformations include rules for recursion formation, conditional formation, and procedure formation. A goal given as input is transformed into subgoals until a primitive program to accomplish it is derived. Strategic controls are used to choose among possible synthesis paths.

Burstall and Darlington [BD 75] described a formal system for manipulation and optimization of recursive functions. The language they use is that of recursion equations. Darlington [D 75] extended this language to include set notation (having been influenced by the work of Manna and Waldinger), and described the application of the transformation system to the problem of program synthesis. (The difference between program transformation and program synthesis lies in the degree of abstraction in the specification one starts with.) Non-trivial algorithms have been derived manually using the transformation rules of the system, however cleverness is still needed at some points to determine which rules to apply.

Clark and Sichel [CS 77] describe the process of deriving computational logic programs (defined by Sichel [S 77a]) from axiomatic specifications. The process was investigated using hand synthesis of programs, but an interactive system was intended

to be implemented that would become more automatic as the synthesis methodology was refined. Clark and Darlington [CD 78] further this methodology using a compromise notation of logic and recursion equations, making the results applicable in both formalisms. They describe the synthesis of recursive function definitions from axiomatic specifications. Sickel [S 77a] also described a methodology for continuing the process down to an executable form in a "conventional" programming language. By doing a theorem proving style of analysis of the logic program one can derive a tree representing all possible proofs of the program taken as a theorem. A regular expression is used to describe a computation path representing all proofs of the theorem. This computation path may then be mapped into a program in the target programming language.

Observing that the structure of a program is often determined by the structure of the data it operates on, von Henke [H 75] organized knowledge about the data domain and represented it in such a way that it can directly assist a system in constructing programs. He used LCF (Logic for Computable Functions), extended to include terms for expressions involving sets and bounded quantification, as the problem specification language. The fact that every LCF term also has an interpretation as a computational rule for the function denoted by it allows the term to be regarded as a program. Data type definitions are used to generate "characterizing" functions (identity on the type defined and undefined elsewhere) which can then be abstracted into functionals for homomorphic and endomorphic extension. For instance, a predicate to recognize the type could be described as a homomorphic

extension into truth values. A function to accomplish substitution, "replace free occurrences of v in e by t after renaming bound variables in e so that no free variable in t becomes bound in the modified e ", can be expressed as an endomorphism on the data type "expressions".

All of the approaches mentioned above deal with formal systems in which the proofs of equivalence of program and specification can be carried out. Many researchers have experimented with systems that automatically write or modify programs from partial specifications in an ambiguous language (subsets of English), making correctness more difficult to arrive at. Heidorn [H 76] reviews four such projects that use natural language dialogues with the machine for specification of the problem. Most such projects limit the area of application severely. In his own research at the NPS (Naval Postgraduate School, Monterey, Ca.) Heidorn used a restricted form of English as input and generated GPSS programs as output. The system used hundreds of decoding and encoding rules and was designed for generation of programs to do queueing simulations. These it did well with the author of the system as user.

Another project aiming at natural language specification is being carried on at the Information Sciences Institute of the University of Southern California. This system, called SAFE [BGW 77], is intended to be independent of the problem domain, and consists of three phases: "domain acquisition" [GBW 78], "planning" [WBG 77], and a phase to produce the final program. The input to the system is a (manually) parenthesized natural language program description retaining most semantic

ambiguities of natural language but avoiding its syntactic ambiguities. The phases deal with the data and operation structure, the program and control structure, and the program variable and parameter structure, respectively.

Lenat [L 75] studied the problems involved in synthesizing large LISP programs requiring several hours of user-system interaction time to generate natural language specifications for the problem. The problem domain was inductive inference programs. The system was made up of BEINGs, experts on various topics (such as coding, probability, or contradiction), capable of asking and answering questions of the user or other BEINGs. It was found that to be successful a user had to be "familiar with LISP, well-grounded in computer science, and have the input-output behavior clearly in mind." The system was constructed with particular dialogues in mind. Problems pointed out by the experiment were the inflexibility of the system to new dialogues, its dependence on user reliability (no errors allowed), and the system's inability to accept new high level domain-specific knowledge (these additions had to be made through modifications of the system itself).

Another approach is synthesis of programs by example. Hardy [H 75a] describes a system that generates LISP functions from a single input-output pair. He deals only in the domain of list-manipulating functions and claims that "despite the fact that there are infinitely many functional extensions of the input-output

('iopair'): (A B C D) = > = ((A) (B) (C) (D))

there is only one function that would be regarded as the 'obviously' intended one." This is certainly true, and he has quite a few examples that work as one might expect.

However one can imagine several functions incapable of being completely characterized by a single input-output pair, e.g., any function which operates differently as the result of a test on the data it receives as an argument (if the first element of an integer list is even then ...).

Summers [S 77b] uses several sample input-output pairs to synthesize LISP functions. This is accomplished by a series of transformations from a set of examples to a program. Programs are synthesized in a subset of LISP using the primitive functions *car*, *cdr*, *cons*, and *atom*, and the control structures of recursion, functional composition, and the conditional expression. The current system, THESYS, is able to derive programs with at most a single recursive call. A technique called "differencing" is used to set up equations that can be rewritten as a set of recurrence relations which are then used to find the recursive program satisfying the examples. Another technique, "variable addition", is used to generalize on a set of examples with the hope of enabling differencing where it was not applicable before.

Rather than supply example input-output pairs, Ulrich and Moll [UM 77] advocate supplying an entire program as an example and establishing an analogy that the computer can use to derive another program. By extending an analogy, a given program may be used to generate another program solving a different but analogous problem. The analogy formation process works with the proof of the known program rather than with its code. The proof is attempted for the new domain and only altered when a step is not valid in this domain. A change in the correctness proof causes a change in the code. The initial analogy must always be specified by the user, making the solution of subproblems somewhat awkward.

Biermann and Krishnaswamy [BK 76] construct programs from sample computation traces. They have shown that if there exists a program capable of executing the given trace, then their system will find that program (or one equivalent to it). This approach assumes the user has an algorithm already in mind (to supply the computation trace).

Several of the above approaches are brought to bear in a project lead by Green [G 77] at Stanford University. The PSI program synthesis system consists of two phases: an acquisition phase and a synthesis phase. The specification is accomplished through a dialogue with the user, using English descriptions, examples, and traces. The acquisition phase is made up of a parser-interpreter, a trace and examples inference system, a dialogue moderator, a domain expert, and a model builder. The synthesis phase involves the interaction of a coder and an efficiency expert to refine the program model into an efficient executable program. The PSI system is being extended as the group attacks different problem domains.

Specification Language

The input to the system is a sequence of definitions. A target definition specifies the target language to be used, which may be changed during a session by simply supplying another target definition. The other kinds of definitions are function, type and generic.

A function definition has six parts, a name, an input pattern, a formal parameter list, a precondition, a postcondition, and a body.

For example:

```
function Fact
input pattern? (1 0)
parameter list? (x y)
precond? Integer(x, true)  $\wedge$  z(x, 0, true).
postcond? Integer(y, true)  $\wedge$  >(y, 0, true).
body? Fact(0, 1)
      Fact(z, w)  $\leftarrow$  Subl(z, z1), Fact(z1, w1), *(z, w1, w).
```

The verbosity in the indicators is endurable since the system types out the question asking for each part of the specification following the function name. The name part is self-explanatory. An input pattern is a list of 1's and 0's indicating which of the arguments of the function being defined are expected to hold input values and which are used to carry values produced during the computation of the function, respectively.

A formal parameter list is required to match up the appropriate arguments for the precondition and postcondition specifications. As we will see, the formal parameters are independent of the specification of the body.

The precondition is a well-formed-formula of predicate calculus, defined on the input variables, that is true only if the function is defined for those input variables. By specifying precisely the domain of the function we can guarantee termination of each program. The precondition is more than just a type declaration in the usual sense, such as Integer or Real, it may also provide information such as " $x \geq 2$ " assuming that x is an input variable. Similarly, the postcondition is a predicate formula on the output variables that specifies the range of the output. Taken together, the precondition and postcondition specify the functionality, i.e. the domain and range, of the program being defined. The range given may in fact be larger than the actual range of the function, but the domain given must not include any extraneous elements.

A body definition is a set of Horn clauses that describes the function, usually recursively, in an axiomatic way. Each Horn clause is an implication, stating that the goal can be asserted if a set of subgoals can be satisfied. In writing a body definition we are asserting that each of these implications is true.

Formally, a Horn clause is a disjunction of literals (atomic formulas, such as " $P(x, 2, y)$ ", or negated atomic formulas) in which at most one literal is positive (not negated). The implication form is derived from the fact that $(A \vee \neg B \vee \neg C) \equiv (A \leftarrow B \wedge C)$. There are four kinds of Horn clauses:

- 1) one with non-empty antecedent and consequent;
- 2) one in which the antecedent is empty and the consequent is non-empty;
- 3) a clause with non-empty antecedent and an empty consequent; and
- 4) an entirely empty clause.

Only the first two of these types of clauses are used in function definitions. The first is an implication as mentioned above, the second is considered an assertion. (The assertion arises from the fact that we can consider the form of the implication to be a conjunction implying a disjunction, an empty conjunction is interpreted as true, thus asserting the implication " $\text{true} \rightarrow A$ " is the same as asserting " A ".) Kowalski [K 74] describes the interpretation of Horn clauses as a programming language. We will discuss the differences between Logic programs and the specifications required by this system in a later section; see page 28.

A type definition is essentially a definition of the predicate that recognizes occurrences of the type. In this sense it has the same form as any other function definition. The body of a type definition has the same form as that of a function definition. For the sake of consistency, we require that each type predicate have an output variable, just as any other function definition would. Although one may not usually think of a predicate as needing an output variable, since the evaluation of the predicate succeeds if and only if the answer is "true", the inclusion of an explicit output variable allows us to distinguish when it is possible to give an answer of "false" from the case in which we simply cannot determine that the answer is "true".

For example,

```

type Set
body? Set(Mt-set, true)
Set( Add-elm(y,X), true) ← Set(X, true), Member(y, X, false).

```

Much of the information is implicit in a type definition. The input pattern is always (1 0), the formal parameter list is any list of two variables, the precondition is *TRUE*, and the postcondition is simply that the output variable ends up with a truth value.

A generic function is one in which the input pattern is allowed to vary. For example, one might wish to define a function "*Concat(x, y, z)*", meaning "*z* is the result of appending *x* and *y*". If defined as a generic function we can use *Concat* in defining other functions whenever we have two of its arguments available and wish to compute the third.

The definition of a generic function includes its name, a formal parameter list (again for the purposes of the preconditions and postconditions), a list of choices specifying how the function may be used, and possibly more than one body definition.

The general form of a generic specification is ²:

```

"generic" name
"parameter list?" id-list
"choices?"
input-pattern1
  "function name?" funname1
  "precond?" precondition1
  "postcond?" postcondition1
  "body-name?" bodyname1
...
input-patternn

```

²The subscripts used are for clarity in the example; they are not part of the syntax.

```

"function name?" funnamen
"precond?" preconditionn
"postcond?" postconditionn
"body-name?" bodynamen "."

"body-defs:"
name1 "?" h-clause1* "."
...
namek "?" h-clausek* "."

```

A choice is made up of an input pattern, a name to be associated with this particular style of call on the function, domain and range specifications, and a body name indicating the function body to be used. A body definition associates a body name with a definition (i.e. a set of Horn clauses).

3.1 Syntax of the Specification Language

A context-free description of the input language is as follows:
PHRASE STRUCTURE:

```

input ::= definition* "."
definition ::= fun-def | type-def | gen-def | target-def
fun-def ::= "function" name
           "input pattern?" input-pattern
           "parameter list?" id-list
           "precond?" precondition
           "postcond?" postcondition
           "body?" h-clause* "."
type-def ::= "type" name
           "body?" h-clause* "."
gen-def ::= "generic" name
           "parameter list?" id-list
           "choices?" [choice "choices?"]* "."
           "body-defs:" body-def*
target-def ::= "target" target-language
target-language ::= name

```

```

choice ::= input-pattern
         "function name?" name
         "precond?" precondition
         "postcond?" postcondition
         "body-name?" name

body-def ::= name "?" h-clause* "."

input-pattern ::= "(" zero-or-one* ")"
zero-or-one ::= "0" | "1"
name ::= identifier
id-list ::= "(" name* ")"
precondition ::= disjunction "."
postcondition ::= disjunction "."
disjunction ::= conjunction | conjunction "v" disjunction
conjunction ::= literal | literal "^" conjunction
literal ::= "True" | "T" | pred-app | "(" disjunction ")"
pred-app ::= name arglist
arglist ::= "(" arg* ")"
arg ::= fun-app | variable | constant
fun-app ::= name arglist
variable ::= identifier
h-clause ::= goal "+" subgoals | goal
goal ::= pred-app
subgoals ::= pred-app [ "," pred-app ]*
constant ::= number | string | "true" | "t" | "false" | "f"
           | "undef" | "(" ")" | quoted-const
string ::= dblquote [ anychar | punctuation | dblquote dblquote | " " ]* dblquote
punctuation ::= ";" | "." | ":" | "," | "<" | ">" | "/" | "<"/>" | "(" | ")"
variable ::= identifier
quoted-const ::= "'" exp
exp ::= identifier | "(" elem* ")"
elem ::= constant | variable | exp

```

$$S[h\text{-}clause^*] \wedge ((S[name] S[id\text{-}list]) \rightarrow S[postcondition])^3$$

where:

the semantic function S maps elements of the specification language onto their denotations in first-order logic. Due to the similarity of the languages involved, this mapping is the identity mapping for the *id-list*, *input-pattern*, and *name*. The denotations of the *precondition* and *postcondition* are the obvious formulas of first-order logic. Elements of the semantic domain will be given in bold type whenever a distinction is desired.

\bar{x} represents all variables in $S[id\text{-}list]$

$inputs[S[id\text{-}list], S[input\text{-}pattern]]$ is the list of input parameters, i.e., those parameters in $S[id\text{-}list]$ corresponding to 1's in $S[input\text{-}pattern]$

$defined[u]$ is true iff every element of the list u has a value that is completely defined (contains no free variables)

$S[h\text{-}clause^*]$ is the conjunction of the semantics of the individual horn clauses. The semantics of each horn-clause is that for all variables mentioned, the conjunction of the right-hand-side implies the left-hand-side.

$S[name id\text{-}list]$ is the denotation of the application of $S[name]$ to $S[id\text{-}list]$ in first-order logic.

For example:

```
function Fact
input pattern? (1 0)
parameter list? (x y)
precond? Integer(x, true)  $\wedge$  z(x, 0, true).
postcond? Integer(y, true)  $\wedge$  >(y, 0, true).
body? Fact(0, 1)
      Fact(z, w)  $\leftarrow$  Subl(z, z1), Fact(z1, w1), *(z, w1, w).
```

has the semantics of the associated first order logic expression:

$$\begin{aligned} \forall x, y [& defined[(x)] \wedge Integer(x, true) \wedge z(x, 0, true) \rightarrow \\ & Fact(0, 1) \\ & \wedge \forall z, z1, w, w1 [(Subl(z, z1) \wedge Fact(z1, w1) \wedge *(z, w1, w) \rightarrow Fact(z, w))] \\ & \wedge [Fact(x, y) \rightarrow Integer(y, true) \wedge >(y, 0, true)]] \end{aligned}$$

The semantics of a type specification:

```
"type" name
"body?" h-clause* "."
```

³We assume that the logical operators have the following precedence relationships, from tightest to least binding: \neg , \wedge and \vee , \rightarrow , $=$ or \leftrightarrow .

is given by the first order logic formula:

$$\forall x \text{ defined}[x] \rightarrow S[h\text{-clause}^*] \\ \wedge [S[\text{name}(x, y)] \rightarrow \text{boolean}(y, \text{true})]$$

The antecedent of the implication guarantees that we have an input value, the consequent asserts the conjunction of the Horn clauses making up its body and the fact that the result of a type predicate is a truth value. The precondition is "True" (and therefore need not even appear in the antecedent of the implication) since we want to allow anything at all as input to a type predicate, the postcondition need not be stated explicitly in the specification since it is always the same.

The semantics of a generic function specification ⁴:

```
"generic" name
"parameter list?" id-list
"choices?"
input-pattern1
  "function name?" funname1
  "precond?" precondition1
  "postcond?" postcondition1
  "body-name?" bodyname1
...
input-patternn
  "function name?" funnamen
  "precond?" preconditionn
  "postcond?" postconditionn
  "body-name?" bodynamen "."
"body-defs:"
name1 "?" h-clause*1 "."
...
namek "?" h-clause*k "."
```

is given by the conjunction:

$$\bigwedge_{i=1}^n \forall x [(S[\text{funname}_i, \text{id-list}] \rightarrow S[\text{name id-list}]) \wedge \\ (\text{defined}[\text{inputs}[S[\text{id-list}], S[\text{input-pattern}_i]]) \wedge S[\text{precondition}_i] \rightarrow \\ S[\text{H-C}[\text{bodyname}_i]] \wedge (S[\text{funname}_i, \text{id-list}] \rightarrow S[\text{postcondition}_i]))]$$

⁴Note again that the subscripts are not part of the syntax

where:

H-C[*bodyname*_{*i*}] is the *h*-clause*_{*i*} associated with *bodyname*_{*i*},
the *input-pattern*_{*i*}'s are distinct,
the *funname*_{*i*}'s are distinct,
the *bodyname*_{*i*}'s need not be distinct,
the *name*_{*i*}'s are all distinct and are all the different *bodyname*_{*i*}'s listed above,
and S is the identity mapping on *bodyname*'s and *funname*'s.

Thus the generic specification has the effect of defining several different functions and associating them all with a "generic" name that can be used when one does not wish to bother with using a different name every time the function is called in a different way, that is, with a different input-pattern.

The semantics of a target definition is simply the ordinary Hoare rule for assignment:

P[name/target] { target name } P

Using this specification language we can describe an algorithm for unification of two lists of terms as follows:

```

function Unify
input pattern? (1 1 0)
parameter list? (t1 t2 s)
precondition? List(t1, true)  $\wedge$  List(t2, true).
postcondition? Substitution(s, true).
body?  Unify( (), (), ())
        Unify( (), cons(x,u), undef)
        Unify(cons(x,u), (), undef)
        Unify(cons(x,s1), cons(y,s2), s)  $\leftarrow$  Unifyterms(x, y, s1),
        Mk-subst(s1, t1, t2, newt1, newt2),
        Unify(newt1, newt2, s2),
        Compose-subs(s1, s2, s).

```

Logic Programming versus Synthesis

Predicate logic can be viewed as a powerful, high level, nondeterministic programming language. Why not simply program in logic instead of bothering with a system to obtain programs in some other language? For one thing, logic is often more powerful than we need, and this power is not free. The full backtracking abilities required by an implementation of logic can be costly in time and space. Also, some languages are better suited to particular problems than are others. Although the style of program generated by the system proposed here is inherited from the specification and therefore similar in all languages, a program transformation system may be constructed that could optimize programs in a specific language to take advantage of its special features. The main purpose of the synthesis system is to see that we end up with correct programs. In this section we look at logic as a programming language, and then as part of the specification language for this system.

The completeness of the Horn clause subset of predicate logic as a programming language has been proven by Andreka and Nemeti [AN 76]. The operational semantics has been found [EK 74] to be part of the proof theory of predicate calculus and thus closely related to the axiomatic semantics. The operational semantics involves consideration of all possible derivations from the axioms. This implies, among other things, the ability to compute relations, not just functions. For example, the operational semantics of the atomic formula $Times(x, y, z)$, would be described as follows:

$$(a, b, c) \in D_{op}[Times] \text{ iff } (a, b, c) \in \{ (x, y, z) \mid \vdash_{\lambda} Times(x, y, z) \}$$

where λ is the theory of predicate calculus augmented by the definitions given as axioms. A computation of $Times(3, 4, x)$ would find only one answer, with $x=12$. However, a computation of $Times(x, y, 12)$ would involve several derivations: $Times(1, 12, 12)$, $Times(12, 1, 12)$, $Times(2, 6, 12)$, $Times(6, 2, 12)$, $Times(3, 4, 12)$, and $Times(4, 3, 12)$, (in some order). The computation of $Times(3, y, z)$ would never terminate since there are an infinite number of derivations possible.

There is no distinction made between input and output. A given tuple is in a particular relation or not. This facet of logic programming is particularly useful in data base applications [E 78].

There is no order of evaluation implied by a logic program. Its operational semantics involve all derivations without indicating which should be attempted first. Thus, a logic program, together with a call on it, determines a computation tree but says nothing of which path to follow. Under these circumstances, to prove termination of a logic program, one must prove the tree is finite.

In any given implementation of a logic interpreter things are not that bad. The order of evaluation is deterministic, so the tree is always traversed in a predictable way. Even so, if all derivations are to be attempted, termination occurs only for finite trees. However, termination can be proved under some circumstances. For example, if only a single answer rather than *all* answers is desired, then one may be able to prove termination for a particular order of evaluation with respect to specific argument positions being designated for inputs.

In the current system we have chosen to define functions rather than relations, in the sense that we want a single unique answer to a question rather than all possible answers. This decision is based on the belief that a programmer knows when *the* answer, *any* answer, or *all* answers to a problem is desired and can design the program to ask for such explicitly. Asking for the answer "the set of all frames that foo" is a request for a single unique answer.

The specification of a function includes a Horn clause description. The specification is translated into a deterministic algorithm expressed in an intermediate language. Currently, clauses are tried in the order given as are subgoals within a clause. An automatic ordering is under consideration by Mike Fransich at the University of California at Santa Cruz. Some analysis can be done to ensure, for example, that termination cases are attempted first, and subgoals that produce values are called before other subgoals that need those values as input.

We distinguish between input and output variables for two reasons. First, given which values are expected to be available and which are to be computed, we can often

prove termination when in the general case we may not be able to (for instance, in the *Times*(x, y, z) example discussed earlier). Also, perhaps more importantly, we believe that programs tend to be based on the construction of the variables one expects to compute. The programmer is more likely to see a task as deriving output information from given input information than as a non-directional exploration of the relationship between the two. Thus, even if the program terminates when inputs and outputs are interchanged, the computation may become horribly inefficient.

Programs can be written that are "nicely" invertible, meaning that one direction of computation is about as efficient as another. In logic programs invertibility is more general than simply swapping of input and output variables; we are dealing with n -tuples not ordered pairs. Thus, for an n -ary predicate there are 2^n different ways of designating input and output variables. Sickel [S 78] describes j -invertibility, referring to the j th variable of the n -tuple. She presents some guidelines for constructing invertible functions, and describes algorithms to test the invertibility of programs.

Since it can often be useful to describe one procedure that may be used in different ways, we have included the concept of a "generic function"⁵. We wish to

⁵According to the dictionary, "generic" means "applicable or referring to all the members of a genus or class". A "generic" function is mentioned elsewhere in the literature as a function whose specific form is determined by the data type of its arguments. We are extending this notion to include functions whose "input patterns" (determining which formal parameters are to be expected as input when a function is

allow the convenience of invertible functions while requiring the programmer to be aware of the possibilities in the program. Thus, we require that one list the different calling styles by input-pattern and indicate a function body (set of Horn clauses) to be used in each case. A predicate with six different (useful) calling styles may use the same logic program as the specification for three input-patterns, another for two input-patterns, and a third for the last. Thus we get the best of both worlds; we know enough to maintain the guarantee of termination, and the user gains the flexibility afforded by a generic function in the specification of other programs. The system attaches a different name to each function body and determines from context which is appropriate in a given instance of the generic.

called) may vary. The implementation of the generic chosen by type rather than input pattern is suggested as an extension of the current system .

Intermediate Language

The intermediate language form of function definitions is strictly for use by the system. The user never sees or programs anything in the internal form. The auxiliary specifications (all but body specifications) are essentially unchanged; their representation is slightly different but exactly the same information is expressed. Thus, the only really interesting part of the intermediate form is its treatment of the body specification.

The body of a function in internal form is a "backtracking-conditional" ("bktrkcond" for short). The name is slightly too general as only a restricted, well behaved, kind of backtracking is allowed. Each clause of the specification becomes an "alternative" in the bktrkcond. An alternative consists of a "match"-part, which is an argument list to be matched against the actual parameters of a function call, and a

"try" part consisting of the subgoals to be accomplished. If the match-part of an alternative is accomplished, then the actual call on the function is an instantiation of the head (or goal) part of the clause from which the alternative was derived. Thus, according to the specifications, we can assert this call if it is possible to accomplish all the subgoals. If the match-part succeeds then we attempt the try-part of the alternative. If the try-part is successful, then we are done; if not, then we must look for another alternative. The backtracking involved is well-behaved in the sense that we backtrack only over entire alternatives, never over individual subgoals in the try-part of an alternative. All that must be undone is the bindings made in accomplishing the unification of the actual parameter list with the argument list in the match-part of the alternative.

We impose determinism on the program at this stage by insisting on a particular order for considering the alternatives: the order in which the user supplied them to the system. An extension to the system is desired that would analyze the alternatives and decide for itself what order would be most effective. The ordering of the subgoals is also open to question. These issues are being investigated by M. Franusich, a student at UCSC, and we hope to incorporate his results eventually.

The intermediate form of a generic specification involves two things. First, the intermediate form of a generic definition contains only the parameter list of the function and a list associating input-patterns with the function name to be used when that input-pattern is recognized. Although it does not appear in the internal generic definition, a generic specification causes the function definitions for each alternative version of the function to be made.

The Intermediate Language is similar to the Input Language in many ways. To point out the similarities, we have used the same nonterminal names where applicable. All the nonterminals are prefixed with a "\$" to distinguish them from those of the Input Language.

5.1 Syntax of Intermediate Language

A context-free grammar describing the Intermediate Language is:

PHRASE STRUCTURE:

```

program ::= $definition*
$definition ::= $fun-def | $type-def | $gen-def | $target-def
$fun-def ::= "(" "function" $name $input-pattern $id-list
             $precondition $postcondition $body ")"
$type-def ::= "(" "type" $name "(1 0)" "(x y)" "T" "(boolean y)" $body ")"
$gen-def ::= "(" "generic" $name $id-list $selection* ")"
$target-def ::= "(" "setq" "target" $target-language ")"
$target-language ::= $name
$selection ::= $input-pattern $name
$input-pattern ::= "(" $zero-or-one* ")"
$zero-or-one ::= "0" | "1"
$name ::= $identifier
$id-list ::= "(" name* ")"
$precondition ::= $disjunction
$postcondition ::= $disjunction
$disjunction ::= $conjunction | "(" "v" $conjunction $disjunction ")"
$conjunction ::= $literal | "(" "w" $literal $conjunction ")"
$literal ::= "T" | $pred-app | $disjunction
$pred-app ::= "(" $name $arg* ")"
$body ::= $backtracking-conditional

```

$\$backtracking\text{-}conditional ::= "(" \text{"bktrkcond"} \$alternatives ")"$
 $\$alternatives ::= \$match\text{-}try\text{-}pair^*$
 $\$match\text{-}try\text{-}pair ::= "(" \$arglist \text{"try"} \$subgoals ")"$
 $\$arglist ::= "(" \$arg^* ")"$
 $\$arg ::= \$fun\text{-}app \mid \$variable \mid \$constant$
 $\$fun\text{-}app ::= "(" \$name \$arg^* ")"$
 $\$subgoals ::= \$pred\text{-}cpp^*$
 $\$variable ::= identifier$
 $\$constant ::= number \mid \$string \mid "true" \mid "false" \mid "undef" \mid "(" \mid ")" \mid \$quoted\text{-}const$
 $\$string ::= "(" \text{"string"} \$char\text{-}list ")"$
 $\$char\text{-}list ::= "(" [anychar \mid \$punctuation \mid dblquote \mid " "]^* ")"$
 $\$punctuation ::= ", \mid "/ \mid "\" \mid "/" \mid "; \mid ":" \mid "/" \mid "/" \mid "/" \mid "(" \mid ")"$
 $\$quoted\text{-}const ::= "(" \text{"quote"} \$exp ")"$
 $\$exp ::= identifier \mid "(" \$elem^* ")"$
 $\$elem ::= \$constant \mid \$variable \mid \exp

The LEXICON is the same as for the specification language.

5.2 Semantics of the Intermediate Language

The semantics of the intermediate language form of a function definition:

$\$fun\text{-}def ::= "(" \text{"function"} \$name \$input\text{-}pattern \$id\text{-}list \$precondition$
 $\$postcondition \$body ")"$

is given by the first order logic formula:

$\forall \bar{x} \text{ defined}[\text{inputs}[S[\$id\text{-}list], S[\$input\text{-}pattern]]] \wedge S[\$precondition] \rightarrow$
 $S[\$body] \wedge (S[\$name \$id\text{-}list] \rightarrow S[\$postcondition])$

where:

the semantic function S maps elements of the intermediate language onto their denotations in first-order logic. This is the obvious mapping for $\$id\text{-}list$, $\$input\text{-}pattern$, $\$name$, $\$precondition$, and $\$postcondition$. (see page 25)
 \bar{x} represents all variables in $S[\$id\text{-}list]$

$\text{inputs}[S[\$id\text{-list}], S[\$input\text{-pattern}]]$ is the list of input parameters, i.e., those parameters in $S[\$id\text{-list}]$ corresponding to 1's in $S[\$input\text{-pattern}]$
 $\text{defined}[I]$ is true iff every element of the list I has a value that is completely defined (contains no free variables)
 and the semantics of the function body $S[\$body]$ is given below.

The intermediate form of a function body is:

$$\begin{aligned}
 & (" \text{bktkcond} " (" \$arglist_1 (" \text{try} \$subgoals_1 ") ") " \\
 & \quad \vdots \\
 & (" \$arglist_n (" \text{try} \$subgoals_n ") ") ") "
 \end{aligned}$$

Informally, the semantics can be expressed as a conjunction of implications each of which states that if the values bound to the $\$id\text{-list}$ are an instantiation of $\$arglist_i$, then the conjunction of all the subgoals in $\$subgoals_i$ implies $(\$name \$arglist_i)$. Of course any substitutions necessary to unify the $\$id\text{-list}$ and $\$arglist_i$ must be made throughout the $\$subgoals_i$.

We actually want an "ordered" conjunction, to ensure that the implications involved in each alternative are considered in the order given. We want to say that if both antecedents in the implication are true then we can successfully claim the consequent and do not wish to consider the remaining implications as applicable; however, if either antecedent is false, then we want to proceed looking for an implication that is "useful" to us.

Let us represent by σ_i the substitution applied to unify ⁶ $\$arglist_i$ with $\$id\text{-list}$, if such a unification is possible. For all A , $A\sigma_i$ is A with all substitutions in σ_i made.

⁶Unification is the process of finding a "most general substitution", in the sense of making as few bindings as possible, which will render the objects being unified to be syntactically identical. See [D 76], or [M 64] for a complete definition.

Expressed as a formula of first order logic:

$$\bigwedge_{i=1}^n [(\text{unify}[S[\$id-list], S[\$arglist_i]] = \sigma_i) \wedge \bigwedge_{j=1}^m (\neg b_j) \rightarrow \\ (S[\$subgoals_i, \sigma_i] \rightarrow S[\$name \$arglist_i, \sigma_i])]$$

where:

S is again obvious on $\$arglist$'s and $\$subgoals$'s

b_j stands for $(\text{unify}[S[\$id-list], S[\$arglist_j]] = \sigma_j) \wedge S[\$subgoals_j, \sigma_j]$

$S[\$subgoals_i, \sigma_i]$ is the conjunction of all subgoals in $\$subgoals_i$

with the substitution σ_i made throughout,

and all free variables are universally quantified.

The semantics of a type definition is, again, very similar to that of a function definition. The semantics of the type definition:

$$(" \text{"type"} \$name "(1 0)" "(x y)" "T" "(boolean y)" \$body ")$$

is given by the formula:

$$\forall x \text{ defined}[(x)] \rightarrow S[\$body] \wedge ((S[\$name (x y)]) \rightarrow S[(boolean y)])$$

where $S[\$body]$ is as defined above for function bodies.

The semantics of a generic definition:

$$(" \text{"generic"} \$name \$id-list \\ \$input-pattern_1 \$name_1 \\ \dots \\ \$input-pattern_n \$name_n ")$$

is given through an association of a call on $\$name$ with the $\$name_i$ determined by the positions of the arguments having values at the time the function is called. Formally:

$$\bigwedge_{i=1}^n \forall x [\\ S[\text{def-of}[\$name_i]] \wedge (S[\$name_i \$id-list] \rightarrow S[\$name \$id-list])]$$

where: $S[\text{def-of}[\$name_i]]$ is the semantics of the function definition of $\$name_i$.

i.e.,

$$\forall x \text{ defined}[\text{inputs}[S[\$id-list], S[\$input-pattern_i]]] \\ \wedge S[\$precondition_i] \rightarrow$$

$$S[\text{body-of}(\$name_i)] \wedge (S(\$name, \$id\text{-list}) \rightarrow S[\$postcondition_i])$$

The semantics of a target definition:

$$(" \text{"setq" "target" \$name "}")$$

is the Hoare rule for assignment:

$$P[\$name/target] \{ (\text{setq target \$name}) \} P$$

Mapping From Input Specification to Intermediate Form

We now define the mapping / (for "internalize") from input specifications into intermediate language. In the first column we identify the input form being translated, the center column shows the translation, and the third column relates nonterminals of the input language to the instance being translated. Since the lexicon for both languages is the same, the translation is concerned only with the phrase structure of the languages.

$\mathcal{I}(\text{input}) =$	$\mathcal{I}(\text{definition}^*)$	$\text{input} = \text{definition}^*$
$\mathcal{I}(\epsilon) =$	ϵ	where ϵ is the empty string
$\mathcal{I}(\text{definition}_1 \text{ definition}^*) =$	$\mathcal{I}(\text{definition}_1) \mathcal{I}(\text{definition}^*)$	
$\mathcal{I}(\text{definition}) =$	$\mathcal{I}(\text{fun-def})$	$\text{definition} = \text{fun-def}$
$\mathcal{I}(\text{definition}) =$	$\mathcal{I}(\text{type-def})$	$\text{definition} = \text{type-def}$

<i>l[definition]</i> =	<i>l[gen-def]</i>	<i>definition</i> = <i>gen-def</i>
<i>l[definition]</i> =	<i>l[target-def]</i>	<i>definition</i> = <i>target-def</i>
<i>l[fun-def]</i> =	"(function" name <i>input-pattern</i> <i>id-list</i> <i>l[precondition]</i> <i>l[postcondition]</i> "(" "bktrkcond" <i>l[h-clause*]</i> ")" ")"	<i>fun-def</i> = "function" name "input pattern?" <i>input-pattern</i> "parameter list?" <i>id-list</i> "precond?" <i>precondition</i> "postcond?" <i>postcondition</i> "body?" <i>h-clause* .</i>

The function I is the identity mapping on *name's*, *id-list's*, and *input-pattern's*, and on *precondition's* and *postcondition's* it is simply a translation to a fully parenthesized prefix form of representation.

$\lambda[\text{precondition}] =$	$\lambda[\text{disjunction}]$	<i>precondition = disjunction "."</i>
$\lambda[\text{postcondition}] =$	$\lambda[\text{disjunction}]$	<i>postcondition = disjunction "."</i>
$\lambda[\text{disjunction}] =$	$\lambda[\text{conjunction}]$	<i>disjunction = conjunction</i>
$\lambda[\text{disjunction}] =$	$"(\vee \lambda[\text{conjunction}]$ $\lambda[\text{disjunction}])"$	<i>disjunction =</i> <i>conjunction "\vee" disjunction</i>
$\lambda[\text{conjunction}] =$	$\lambda[\text{literal}]$	<i>conjunction = literal</i>
$\lambda[\text{conjunction}] =$	$"(\wedge \lambda[\text{literal}]$ $\lambda[\text{conjunction}])"$	<i>conjunction =</i> <i>literal "\wedge" conjunction</i>
$\lambda[\text{literal}] =$	$"T"$	<i>literal = "TRUE"</i>
$\lambda[\text{literal}] =$	$"T"$	<i>literal = "T"</i>
$\lambda[\text{literal}] =$	$\lambda[\text{pred-app}]$	<i>literal = pred-app</i>
$\lambda[\text{literal}] =$	$\lambda[\text{disjunction}]$	<i>literal = "(" disjunction ")"</i>
$\lambda[\text{pred-app}] =$	$\lambda[\text{name arglist}]$	<i>pred-app = fname 'arglist</i>

⁷The internalized form of a generic application will have a different name

$l[name\ arglist] =$	$(" name\ l[arg^*] ")$	$arglist = (" arg^* ")$

$l[fun-app] =$	$l[name\ arglist]$	$fun-app = name\ arglist$
$l[string] =$	$(" "string"$ $l[anychar\ punctuation$ $ dblquote\ dblquote\ " ^*] ")$	$string = dblquote$ $[anychar\ punctuation$ $ dblquote\ dblquote$ $ " ^* dblquote$
$l[anychar\ punctuation$ $ dblquote\ dblquote\ " ^*] =$	$(" [l[anychar]$ $ l[punctuation]$	

substituted for the name of the generic if it appears in the specification of the body of a function. This is why we listed *name* as the translate of *fname* above. The name which is chosen will depend on the input pattern of the function being specified.

		/{dblquote dblquote}
		/{" " }* " " "
/[anychar] =	anychar	
/[punctuation] =	punctuation	punctuation = ", " ". " "" "" ", " ". "
/[dblquote dblquote] =	dblquote	
/[" "] =	" / "	
/[quoted-const] =	"(" "quote" /{exp} ")"	quoted-const = "" exp
/[exp] =	identifier	exp = identifier
/[exp] =	"(" /{elem*} ")"	exp = "(" elem* ")"
/[elem ₁ elem*] =	/[elem ₁] /{elem*}	
/[elem] =	/[constant]	elem = constant
/[elem] =	/[variable]	elem = variable
/[elem] =	/[exp]	elem = exp
/[variable] =	identifier	variable = identifier
/[variable] =	/identifier	variable = identifier formal parameters are indicated by a first character "!"

The interesting part of / maps Horn clauses onto the intermediate form of the function body. Whenever an instance of a generic call is encountered in the body of a specification, the first version of the generic whose input pattern is satisfied, i.e. all argument positions corresponding to !'s in the input pattern have values supplied, is

substituted for the generic. Thus we never have to translate generic specifications into the target language; we just translate each specific version.

$$I[h\text{-clause}_1, h\text{-clause}^*] = I[h\text{-clause}_1] I[h\text{-clause}^*]$$

$$I[h\text{-clause}] = I[goal]$$

$$h\text{-clause} = goal$$

$$I[goal] = (" arglist (" try " " ")$$

$$goal = pred\text{-}app$$

$$= name arglist$$

$$I[h\text{-clause}] = (" arglist$$

$$(" try I[subgoals] " " " " "$$

$$h\text{-clause} = goal \leftarrow subgoals$$

$$goal = name arglist$$

$$I[subgoals] = I[pred\text{-}app_1]$$

$$I[[" pred\text{-}app]^*]$$

$$subgoals =$$

$$pred\text{-}app_1 [[" pred\text{-}app]^*]$$

$$I[" pred\text{-}app_1$$

$$[" pred\text{-}app]^*] = I[pred\text{-}app_1] I[" pred\text{-}app]^*]$$

For type specifications we have:

$$I[type\text{-}def] = (" type name "(I O)"$$

$$(" x y) " T " (boolean y t)"$$

$$(" bktrkcond I[h\text{-clause}^*] " " "$$

$$type\text{-}def =$$

$$type name$$

$$body h\text{-clause}^* "."$$

As discussed earlier, one may consider the type definition to be the definition of a predicate to recognize instances of the type. We must make a distinction between a type definition and the recognizer for a type when our target language is strongly typed. This will be discussed in the mapping from intermediate form to target language.

The mapping from the input specification of a generic function to its intermediate form involves not only the internal form of the generic definition but

also that of each of the specific versions of the generic being defined. The function *Select* creates a sequence of *input-pattern fname* pairs from which the choices of individual functions to substitute for generic calls will be made. The function *Make-defs* creates a function definition for each version of the generic. The resulting definitions are identical to those that would have been created if each version were specified explicitly as a *fun-def*.⁸

<i>l(gen-def)</i> ⁹ =	(" "generic" gname id-list Select[[choice "choices?"]*] " Make-defs[id-list, [choice "choices?"]* bodydef*]	<i>gen-def</i> = "generic" gname "parameter list?" id-list "choices?" [choice "choices?"]* " "body-defs:" body-def*
----------------------------------	---------------------------------------------------------------------------------------------------------------------------	----------------------------------------------------------------------------------------------------------------------------------

where:

Select(*ε*) = *ε*

where *ε* is the empty string

Select(*choice*₁ "choices?" [choice "choices?"]*) =
Select(*choice*₁) Select[[choice "choices?"]*]

Select(*choice*) = *input-pattern fname*

choice =

body-def =

bname *h-clause** ". "

Finally,

[*target-def*] = (" "setq" "target"
target-language ")

target-def =

"target" target-language

The target language specification is just information to the system indicating which target language is desired and is of interest only in choosing the mapping from intermediate language to target.

The specification of the factorial function:

function Fact

input pattern? (1 0)

parameter list? (x y)

precond? $\text{Integer}(x, \text{true}) \wedge z(x, 0, \text{true})$.

postcond? $\text{Integer}(y, \text{true}) \wedge >(y, 0, \text{true})$.

body? Fact(0, 1)

Fact(z, w) \leftarrow Sub1(z, z1), Fact(z1, w1), *(z, w1, w).

has the following form in the Intermediate Language:

```
(function Fact (I 0) (I x I y)
  (^ (Integer I x true) (z I x 0 true))
  (^ (Integer I y true) (> I y 0 true))
  (bktkcond ((0 1) (try))
    ((I z I w) (try (Sub! I x I z I)
      (Fact I z I w I)
      (* I z I w I w) ) )
  ) )
```

Correctness of the Mapping to Intermediate Form

We wish to show that the semantics of an input specification is "sufficiently" preserved in the mapping to intermediate form. By "sufficiently" we mean that the semantics of the intermediate form of a function definition is implied by the semantics of the input specification, and furthermore, if every function (or type) P is defined such that for each input tuple, \bar{x}_i , (i.e., tuple with which the function is called) there exists a unique output tuple, \bar{x}_o , such that $P(\bar{x}_o)$ is derivable using the input semantics, then $P(\bar{x}_o)$ is derivable using the semantics of the intermediate form of the definition. We refer to this restriction of requiring uniqueness of the output tuple by saying that we are defining only "functional" relationships.

The semantics of input and internal form are not equivalent because the input semantics may be used several ways to generate proofs. This is due to the

nondeterministic nature of the process of finding proofs. At any stage of a proof, there may be many Horn clauses that are applicable as axioms, and different proof paths may generate different results. However, we have restricted ourselves to defining functional relationships rather than the more general "relations" which may be one-to-many mappings. Thus, no matter what direction the proof takes, there is a unique result. If a function is specified that does not return unique answers, then the resulting program (and any others whose specifications make use of the function) will be partially correct; however we cannot guarantee that any specification using such a function will result in a program that always finds an answer when one exists.

In the intermediate form we are forced to apply the Horn-clauses in a specific order. Due to the determinism introduced we will follow precisely one proof, the same proof, every time a procedure gets called with the same input values. The important point to establish is that whenever a unique answer may be found in the nondeterministic proof process, our deterministic search will find it as well. First, we establish two lemmas.

Lemma 1.1

$$\forall \bar{x} \ S[h\text{-}clause^*] \rightarrow S[l[h\text{-}clause^*]]$$

that is

$$\begin{aligned} \forall \bar{x} \ [\\ \bigwedge_{i=1}^n (\text{name arglist}_i \leftarrow S[\text{subgoals}_i]) \rightarrow \\ \bigwedge_{i=1}^n \\ (\text{unify}[\text{id-list}, \text{arglist}_i] = \sigma_i) \wedge \bigwedge_{j=1}^{i-1} \neg (S[l[\text{subgoals}_j]\sigma_j]) \rightarrow \\ (S[l[\text{subgoals}_i]\sigma_i] \rightarrow S[l[\text{name arglist}_i]\sigma_i]) \] \end{aligned}$$

where $\forall \bar{x}$ stands for the universal quantification of all variables mentioned in the quantified formula.

Proof:

We shall show that for each i , $S[h\text{-}clause] \rightarrow S[I[h\text{-}clause]]$. For the sake of readability we shall leave out the quantifier with the understanding that all variables are universally quantified. Thus, we want to show:

$$\begin{aligned} &(\text{name arglist}_i \leftarrow S[\text{subgoals}_i]) \rightarrow \\ &((\text{unify}[\text{id-list}, \text{arglist}_i] = \sigma_i) \wedge \\ &\bigwedge_{p_i} \neg(S[I[\text{subgoals}_i]\sigma_i]) \rightarrow \\ &(S[I[\text{subgoals}_i]\sigma_i] \rightarrow S[I[\text{name arglist}_i]\sigma_i])) \end{aligned}$$

1. $S[\text{subgoals}_i] \rightarrow \text{name arglist}_i$ hypothesis
2. $[S[\text{subgoals}_i] \rightarrow \text{name arglist}_i]\sigma_i$ $\forall x A(x) \vdash A(t)$
(as many times as necessary, given that we change variable names that are introduced by the substitution in order to ensure that the new variables are *free for*¹⁰ the old.)
3. $[S[I[\text{subgoals}_i]] \rightarrow S[I[\text{name arglist}_i]]]\sigma_i$ from 2., equivalent replacement, and the facts that $S[I[\text{subgoals}_i]] = S[\text{subgoals}_i]$ and $S[I[\text{name arglist}_i]] = S[\text{name arglist}_i]$
4. $S[I[\text{subgoals}_i]\sigma_i] \rightarrow S[I[\text{name arglist}_i]]\sigma_i$ property of substitution
5. $(\text{unify}[\text{id-list}, \text{arglist}_i] = \sigma_i) \wedge \bigwedge_{p_i} \neg(S[I[\text{subgoals}_i]\sigma_i]) \rightarrow (S[I[\text{subgoals}_i]\sigma_i] \rightarrow S[I[\text{name arglist}_i]]\sigma_i)$ $A \rightarrow (B \rightarrow A)$ and 4., and Modus Ponens
6. $(\text{name arglist}_i \leftarrow S[\text{subgoals}_i]) \rightarrow ((\text{unify}[\text{id-list}, \text{arglist}_i] = \sigma_i) \wedge \bigwedge_{p_i} \neg(S[I[\text{subgoals}_i]\sigma_i]) \rightarrow (S[I[\text{subgoals}_i]\sigma_i] \rightarrow S[I[\text{name arglist}_i]\sigma_i]))$ Deduction Theorem, 1., 5.

QED

¹⁰For a formal definition of *free for* see Davis [D 76], Kleene [K 52], or Mendelson [M 64].

The following lemma makes use of two sub-lemmas whose proofs follow it.

Lemma 1.2

$$\forall \bar{x} (Y \rightarrow Y') \vdash \forall \bar{x} (X \rightarrow Y \wedge Z) \rightarrow \forall \bar{x} (X \rightarrow Y' \wedge Z)$$

where X, Y, Y' , and Z are any well-formed-formulas. The proof is given for a single quantified variable. Clearly it can be generalized to any number of variables.

- | | |
|-------------------------------------------------------------------------------------------|--------------------------------------|
| 1. $\forall x(X \rightarrow Y \wedge Z)$ | hypothesis |
| 2. $\forall x(X \rightarrow Y)$ | 1., Lemma 1.2.1 |
| 3. $X \rightarrow Y$ | 2., \forall -elimination |
| 4. $\forall x(Y \rightarrow Y')$ | hypothesis |
| 5. $Y \rightarrow Y'$ | 4., \forall -elimination |
| 6. $X \rightarrow Y'$ | 3.,5., transitivity of \rightarrow |
| 7. $\forall x(X \rightarrow Y')$ | 6., \forall -introduction |

| 5. Y | \wedge -elimination |
| 6. $X \rightarrow Y$ | 3.,5., Deduction Theorem |
| 7. $\forall x(X \rightarrow Y)$ | 6., \forall -introduction |

Lemma 1.2.2

$$\forall x(X \rightarrow Y), \forall x(X \rightarrow Z) \vdash \forall x(X \rightarrow Y \wedge Z)$$

1. $\forall x(X \rightarrow Y)$	hypothesis
2. $X \rightarrow Y$	1., \forall -elimination
3. $\forall x(X \rightarrow Z)$	hypothesis
4. $X \rightarrow Z$	3., \forall -elimination
5. X	hypothesis
6. Y	2., 5., Modus Ponens
7. Z	4., 5., Modus Ponens
8. $Y \wedge Z$	\wedge -introduction
9. $X \rightarrow Y \wedge Z$	5., 8., Deduction Theorem
10. $\forall x(X \rightarrow Y \wedge Z)$	\forall -introduction

We are now in a position to prove our first theorem.

Theorem 1 :

$$S[I[input]] \vdash P(\bar{x}) \Rightarrow S[input] \vdash P(\bar{x})$$

Any proof derived from the semantics of the intermediate form could be derived from the semantics of the input specification. We will show this by determining that the semantics of an input specification implies the semantics of the intermediate form of the specification.

Proof:

Since *input* is a sequence of definitions which gets internalized as a sequence of definitions, we shall show that:

$$S[definition] \rightarrow S[I[definition]]$$

Then the conjunction of the input definitions implies the conjunction of the intermediate language form of those definitions and:

$$S[input] \rightarrow S[I[input]]$$

and thus anything derivable from $S[I[input]]$ can be derived from $S[input]$ by first deriving $S[I[input]]$ and then following the same proof. We must establish two things:¹¹

¹¹Recall that *I* is just the identity mapping on *id-list's*, *input-pattern's*, and *name's*.

1) for function and type definitions ¹²:

$$\begin{aligned}
 & [\forall \bar{x} \text{ defined[inputs[S[id-list], S[input-pattern]] } \wedge S[\text{precondition}] \\
 & \quad \rightarrow S[h\text{-clause}^*] \wedge ((S[\text{name}] S[id-list]) \rightarrow S[\text{postcondition}])] \\
 & \rightarrow \\
 & [\forall \bar{x} \text{ defined[inputs[S[id-list], S[input-pattern]] } \wedge S[\text{precondition}] \\
 & \quad \rightarrow S[\text{precondition}] \wedge ((S[\text{name}] S[id-list]) \rightarrow S[\text{postcondition}])]
 \end{aligned}$$

2) for generic definitions:

$$\begin{aligned}
 & \bigwedge_{i=1}^n \forall \bar{x} [\\
 & \quad (S[\text{funname}_i, \text{id-list}] \rightarrow S[\text{name id-list}]) \wedge \\
 & \quad (\text{defined[inputs[S[id-list], S[input-pattern]] } \wedge S[\text{precondition}_i] \\
 & \quad \rightarrow S[\text{H-C}[\text{body-name}_i]] \wedge (S[\text{funname}_i, \text{id-list}] \rightarrow S[\text{postcondition}_i]))] \\
 & \rightarrow \\
 & \bigwedge_{i=1}^n \forall \bar{x} [\\
 & \quad (S[\text{funname}_i, \text{id-list}] \rightarrow S[\text{name id-list}]) \wedge \\
 & \quad (\text{defined[inputs[S[id-list], S[input-pattern]] } \wedge S[\text{precondition}_i] \\
 & \quad \rightarrow S[\text{precondition}_i] \wedge (S[\text{funname}_i, \text{id-list}] \rightarrow S[\text{postcondition}_i]))]
 \end{aligned}$$

where $\text{H-C}[\text{body-name}_i]$ is the $h\text{-clause}^*$ associated with body-name_i .

1) is of the form $\forall \bar{x} (A \wedge B \rightarrow C \wedge D) \rightarrow \forall \bar{x} (A \wedge B \rightarrow C' \wedge D)$, where we know by Lemma 1.1 that $\forall \bar{x}(C \rightarrow C')$. Thus, this is just an instance of Lemma 1.2 with " $A \wedge B$ " for X , " C " for Y , " C' " for Y' , and " D " for Z .

2) for each i , is of the form $\forall \bar{x} [(A \rightarrow B) \wedge (C \wedge D \rightarrow E \wedge F)] \rightarrow \forall \bar{x} [(A \rightarrow B) \wedge (C \wedge D \rightarrow E' \wedge F)]$. This is just $X \wedge Y \rightarrow X \wedge Y'$, where we know by part 1) that $Y \rightarrow Y'$. For each i , the statement is true, thus the conjunction of statements over all i 's is true.

QED

¹²The semantics of a type definition is the same as that for a function definition. We gave them separately before, pointing out that we know what the id-list , input-pattern , precondition , and postcondition are for type definitions.

Theorem 2:

If each definition is functional with respect to its output variables, that is, if for each function or type P and each input tuple \bar{x} , there exists a unique output tuple, \bar{x}_0 , such that $P(\bar{x}_0)$, then:

$$S[input] \vdash P(\bar{x}_0) \Rightarrow S[I[input]] \vdash P(\bar{x}_0)$$

Proof:

Given a proof of $P(\bar{x})$ from $S[input]$ we can construct a proof from $S[I[input]]$. A clause of the definition of P is applicable if and only if the current goal is an instance of the head of the clause, i.e., there is a σ , such that $\text{unify}[id\text{-list}, arglist] = \sigma$, where $id\text{-list}$ is bound to the actual parameters in the goal. Thus the only time when a clause that is applicable in the proof from $S[input]$ may not be used in a proof from $S[I[input]]$ is when there is a previously listed clause that is also applicable.

Suppose the proof of $P(\bar{x})$ makes use of the clause P_i of the definition of P when there is a clause P_j , $j < i$, that is also applicable. Our proof from $S[I[input]]$ will attempt to prove $P(\bar{x})$ using P_j . We are guaranteed termination of this attempt by the precondition. If we terminate successfully, we will have proved $P(\bar{x})$, since this proof may also be considered a proof from $S[input]$ and we have assumed that \bar{x} is unique. If we terminate unsuccessfully, then we will attempt another clause, possibly P_i now, as in the original proof from $S[input]$, or possibly some P_k , $j < k < i$. We will eventually succeed before attempting P_i , or we will use P_i as we did

in the original proof. The same analysis is applicable to every clause used in the proof of $P(\bar{x})$ from $S[input]$ and thus we can derive $P(\bar{x})$ from $S[input]$.

QED

Mapping the Intermediate Language to LISP

We have chosen to use LISP as the first target language. One may find documentation for the version we use, MACLISP, in [M 74]. We generate "pure LISP" programs, using none of the special features of the MACLISP implementation, however the names of the primitive functions may vary from implementation to implementation. These functions include: *defun*, for defining a function, *putprop*, for putting a property on the property list of an atom, and *get*, for getting a property from the property list. The function *L*, mapping the intermediate language into LISP is defined as follows.

$L[e] =$	e	
$L[\$definition, \$definition^*] =$		$L[\$definition,] L[\$definition^*]$
$L[\$definition] =$	$L[\$fun-def]$	$\$definition = \$fun-def$
$L[\$definition] =$	$L[\$type-def]$	$\$definition = \$type-def$

<pre> L[\$fun-def] = "(putprop ""\$name ""\$input-pattern "inpat)" "(putprop ""\$name ""\$id-list ""params)" "(putprop ""\$name ""\$precondition ""precond)" "(putprop ""\$name ""\$postcondition ""postcond)" "(defun \$name "fexpr (l)" "(bktkcond l ""\$alternatives"))" </pre>	<pre> \$fun-def = "(" "function" \$name \$input-pattern \$id-list \$precondition \$postcondition "(" "bktkcond" \$alternatives ")" ")" </pre>
<pre> L[type-def] = "(putprop ""\$name "(1 0) 'inpat)" "(putprop ""\$name ""(x y)" ""params)" "(putprop ""\$name "T" 'precond)" "(putprop ""\$name "(boolean y) 'postcond)" "(defun \$name "fexpr (l)" "(bktkcond l ""\$alternatives"))" </pre>	<pre> type-def = "(" "type" \$name "(1 0)" "(x y)" "T" "(boolean y)" "(" "bktkcond" \$alternatives ")" ")" </pre>

There is no mapping of generic definitions, only of the specific function definitions involved, and these are identical to that for *fun-def*'s above. The LISP function *bktkcond* evaluates its arguments, binds the results to the formal parameters *actuals* and *list-alts*, and then recursively attempts each alternative until an answer is found or all alternatives have failed, indicating that the answer is undefined. The complete set of definitions of LISP functions that implement the mapping, i.e. definitions for *bktkcond*, *match*, *try*, and all of the subfunctions required, may be found in Section 16.1, beginning at page 162.

The LISP program that is generated from the specification for the factorial function is as follows. The list of *putprop*'s get evaluated only once; they represent global information about the properties of the function. The *defun* is the actual LISP definition of the function.

```

(defun Fact fexpr (l)
  (cond ((true-precond (cons 'Fact l))
    (bktrkcond l
      '(((0 1) (try))
        ((/x /y)
          (try (Sub1 /x /x1)
              (Fact /x1 /y1)
              (* /x /y1 /y))))))
    (t 'undef)))

```

Correctness of the Mapping to LISP Program

We shall show that the semantics of the LISP form of a function or type definition is equivalent to the semantics of the intermediate form of a function or type definition. There is no distinction between function and type definitions in either form.

We have shown earlier that the semantics of the intermediate form of a definition is expressed:

$$\begin{aligned}
 & \forall \bar{x} \text{ defined[inputs[\$id-list, \$input-pattern]] } \wedge \text{\$precondition} \rightarrow \\
 & \wedge_{i=1}^n [\\
 & \quad (\text{unify}[\$id-list, \$arglist_i] = \sigma_i) \\
 & \quad \wedge \wedge_{j=1}^m (\text{unify}[\$id-list, \$arglist_j] = \sigma_j \rightarrow \neg S[\$subgoals, \sigma_j]) \\
 & \quad \rightarrow (S[\$subgoals, \sigma_i] \rightarrow (\$name \text{ \$arglist}_i \sigma_i))] \\
 & \wedge \\
 & \forall \bar{x} \$name \$id-list \rightarrow \text{\$postcondition}
 \end{aligned}$$

Since \$arglist_i and \$id-list are unified by σ_i , we can use \$name \$id-list instead of \$name \$arglist_i in the final consequent of the first conjunct above. Another way of expressing the fact that \$name \$id-list is true is by saying that \$id-list \in \$name, that is, the given tuple is an element of the relation \$name. Before turning our attention to the semantics of the LISP form, we shall rewrite the semantics of the intermediate form in such a way as to facilitate our proof. This rewriting is based on several rules of first-order logic. To make the statements more readable, we shall look at the general form of the rewrite first, and then apply the result to the expression above.

We are going to focus our attention on the first conjunct of the above expression. This is of the form:

$$\forall \bar{x} A \rightarrow \bigwedge_{i=1}^n [B \wedge C \rightarrow (D \rightarrow E)]$$

which is equivalent to

$$\forall \bar{x} A \rightarrow \forall i [B \wedge C \rightarrow (D \rightarrow E)]$$

where actually the quantifier on i is bounded. Since we know there are a finite number of i 's we will not put in the bounds. It should be understood that i ranges over the number of clauses given in the definition.¹³ The above statement is in turn equivalent to

$$\forall \bar{x} A \rightarrow \forall i [(B \wedge C \wedge D) \rightarrow E]$$

Since in our original formula E does not contain any free occurrences of i , this is equivalent to:

$$\forall \bar{x} A \rightarrow [\exists i (B \wedge C \wedge D) \rightarrow E]$$

¹³The "variable" i is not really a variable at all in the formal sense; it is merely an index. We could write out the consequence of the above implication as the conjunction of the indexed statements. We are using the " $\forall i$ " notation because it provides a convenient abbreviation.

Thus our new formulation of the semantics of the intermediate form of a function (or type) definition is:

$$\begin{aligned}
 & \forall \bar{x} \text{ defined[inputs[\$id-list, \$input-pattern]] } \wedge \$precondition \rightarrow \\
 & \quad [\exists i (\text{unify}[\$id-list, \$arglist_i] = \sigma_i \\
 & \quad \wedge \bigwedge_{j=1}^i (\text{unify}[\$id-list, \$arglist_j] = \sigma_j \rightarrow \neg S[\$subgoals_j, \sigma_j]) \\
 & \quad \wedge S[\$subgoals_i, \sigma_i]) \\
 & \quad \rightarrow (\$id-list) \sigma_i \in \$name)] \\
 & \wedge \\
 & \forall \bar{x} (\$id-list \in \$name) \rightarrow \$postcondition
 \end{aligned}$$

The semantics of a LISP form of a definition, such as:

```

(putprop $name $input-pattern 'input)
(putprop $name $id-list 'params)
(putprop $name $precondition 'precond)
(putprop $name $postcondition 'postcond)
(defun $name fexpr (l)
  (cond ((true-precond (cons $name l))
        (bkrkcond l (rest $body-def)))
        (t undef)))

```

is:

$$\begin{aligned}
 & \forall \bar{x} [\text{eval}[(\text{cons } \$name \text{ actuals})] = \sigma \wedge \sigma \neq \text{undef} \rightarrow (\text{actuals})\sigma \in \$name] \\
 & \wedge \forall \bar{x} [(\text{actuals} \in \$name) \rightarrow \$postcondition]
 \end{aligned}$$

where: σ is a substitution or $\sigma = \text{undef}$

actuals is an instantiation of $\$id\text{-list}$

$\$body\text{-def}$ is $(\text{bkrkcond } (\$arglist_1 (\text{cons 'try } \$subgoals_1))$
 $(\$arglist_2 (\text{cons 'try } \$subgoals_2))$
 \dots
 $(\$arglist_n (\text{cons 'try } \$subgoals_n)))$

The actual function definition begins with *defun*, the preceding *putprop*'s simply attach the listed information to the property list of the function being defined. See [MT 79] for a formal axiomatization of the semantics of LISP. Using the definitions of *eval* and $\$name$, we can write:

```

eval[(cons $name actuals)] =
  IF true-precond[(cons $name actuals)]
  THEN bkrkcond[actuals, rest[$body-def]]

```

ELSE undef

thus,

$$\begin{aligned} \text{eval}[(\text{cons } \$\text{name } \text{actuals})] = \sigma \wedge \sigma \neq \text{undef} \\ \text{is equivalent to} \\ \text{true-precond}[(\text{cons } \$\text{name } \text{actuals})] \wedge \text{bkrkcond}[\text{actuals}, \text{rest}[\$ \text{body-def}]] = \sigma \\ \wedge \sigma \neq \text{undef} \end{aligned}$$

So we can rewrite the semantics of the LISP form as:

$$\begin{aligned} \forall \bar{x} [& \text{true-precond}[(\text{cons } \$\text{name } \text{actuals})] \\ & \wedge \text{bkrkcond}[\text{actuals}, ((\$ \text{arglist}_1 (\text{cons 'try } \$\text{subgoals}_1)) \\ & \quad (\$ \text{arglist}_2 (\text{cons 'try } \$\text{subgoals}_2)) \\ & \quad \dots \\ & \quad (\$ \text{arglist}_n (\text{cons 'try } \$\text{subgoals}_n)))] = \sigma \\ & \wedge \sigma \neq \text{undef} \\ & \rightarrow (\text{actuals})\sigma \in \$\text{name}] \\ \wedge \forall \bar{x} [& (\text{actuals} \in \$\text{name}) \rightarrow \$\text{postcondition}] \end{aligned}$$

We need to establish that the above statement is equivalent to the statement of the semantics of the intermediate form of definition given above. We intend to show this by first establishing that:

$$\begin{aligned} \forall \bar{x} [& \text{defined}[\text{inputs}[\$ \text{id-list}, \$ \text{input-pattern}]] \wedge \$\text{precondition}] \rightarrow \\ & [\exists i (\text{unify}[\$ \text{id-list}, \$ \text{arglist}_i] = \sigma_i \\ & \quad \wedge \bigwedge_{j=1}^i (\text{unify}[\$ \text{id-list}, \$ \text{arglist}_j] = \sigma_j \rightarrow \neg S[\$ \text{subgoals}_j, \sigma_j]) \\ & \quad \wedge S[\$ \text{subgoals}_i, \sigma_i]) \\ & \quad \rightarrow (\$ \text{id-list})\sigma_i \in \$\text{name}] \\ & \quad \cdot \\ & [\text{true-precond}[(\text{cons } \$\text{name } \text{actuals})] \\ & \quad \wedge \text{bkrkcond}[\text{actuals}, ((\$ \text{arglist}_1 (\text{cons 'try } \$\text{subgoals}_1)) \\ & \quad \quad (\$ \text{arglist}_2 (\text{cons 'try } \$\text{subgoals}_2)) \\ & \quad \quad \dots \\ & \quad \quad (\$ \text{arglist}_n (\text{cons 'try } \$\text{subgoals}_n)))] = \sigma \\ & \quad \wedge \sigma \neq \text{undef} \\ & \quad \rightarrow (\text{actuals})\sigma \in \$\text{name}] \end{aligned}$$

The expression resulting from distributing the $\forall \bar{x}$ over the equivalence follows easily from this stronger result. First of all, we will simplify the notation. Both $\$ \text{id-list}$ in the

intermediate form and actuals in the Lisp form are names used to refer to instantiations of the formal parameter list. Since these are now within the scope of the same universal quantifier, we shall identify them both by the same name, actuals. We should also mention that precondition and postcondition are names that are being used to stand for the formulas they represent. Each involves some of the elements of the formal parameter list and we shall assume that there is no confusion as to the bindings of these variables even though we do not mention them explicitly in the formula.

Before attempting the main theorem of this section, we need four lemmas:

1. $\text{defined}[\text{inputs}[\text{actuals}, \text{Sinput-pattern}]] \wedge \text{Sprecondition}$
 $\quad \equiv \text{true-precond}[(\text{cons } \text{Sname actuals})]$
2. $\text{unify}[\text{actuals}, \text{Sarglist}_i] = \sigma_i$
 $\quad \equiv \text{match}[\text{actuals}, \text{newversion}[\text{Sarglist}_i]] = \sigma_i \wedge \sigma_i \neq \text{undef}$
3. $S[\text{\$subgoals}] \equiv \text{try}[\text{\$subgoals}] = \sigma \wedge \sigma \neq \text{undef}$
4. $\exists i (\text{unify}[\text{Sid-list}, \text{Sarglist}_i] = \sigma_i$
 $\quad \wedge \bigwedge_{j=1}^n (\text{unify}[\text{Sid-list}, \text{Sarglist}_j] = \sigma_j \rightarrow \neg S[\text{\$subgoals}_j, \sigma_j])$
 $\quad \wedge S[\text{\$subgoals}_i, \sigma_i])$
 \equiv
 $\text{bktrkcond}[\text{actuals}, ((\text{Sarglist}_1 (\text{cons 'try } \text{\$subgoals}_1))$
 $\quad (\text{Sarglist}_2 (\text{cons 'try } \text{\$subgoals}_2))$
 $\quad \dots$
 $\quad (\text{Sarglist}_n (\text{cons 'try } \text{\$subgoals}_n)))] = \sigma$
 $\wedge \sigma \neq \text{undef}$

We intend to show that the top level mapping is correct, however we do not intend to prove the entire implementation correct, so the proofs of these lemmas will be informal and assume correctness of several subfunctions involved.

Lemma 1

$\text{defined}[\text{inputs}[\text{actuals}, \text{Sinput-pattern}]] \wedge \text{Sprecondition}$
 $\quad \equiv \text{true-precond}[(\text{cons } \text{Sname actuals})]$

Proof:

The function true-precond: 1) looks up the \$input-pattern associated with \$name and checks to see that all input positions of actuals have values supplied; then 2) looks up the \$id-list and \$precondition associated with \$name, binds the variables in \$id-list to the values supplied by actuals and evaluates the \$precondition. Thus, true-precond returns "true" if and only if both steps 1) and 2) are successful, i.e., if and only if $\text{defined}[\text{inputs}[\text{actuals}, \text{\$input-pattern}]] \wedge \text{\$precondition}$.

QED

Lemma 2

$$\begin{aligned} & \text{unify}[\text{actuals}, \text{\$arglist}_i] = \sigma_i \\ & \quad \text{match}[\text{actuals}, \text{newversion}[\text{\$arglist}_i]] = \sigma_i \wedge \sigma_i \neq \text{undef} \end{aligned}$$

Proof:

The semantic function unify, attempts to unify its arguments after renaming variables so its arguments have no variable in common. If unification is possible, then unify returns a substitution, if not, then $\text{unify}[\text{actuals}, \text{\$arglist}_i] \neq \sigma$ for any substitution σ , so the result is false.

$\text{newversion}[\text{\$arglist}_i]$ generates a new version of $\text{\$arglist}_i$ in which each variable has been replaced by a newly generated one. Thus, newversion ensures that the arguments to match have been standardized apart. match is a unification algorithm that returns a (most general) substitution σ if its arguments are unifiable by σ , and returns undef if unification is not possible. Thus,

$$\begin{aligned} & \text{unify}[\text{actuals}, \text{\$arglist}_i] = \sigma_i \\ & \quad \text{match}[\text{actuals}, \text{newversion}[\text{\$arglist}_i]] = \sigma_i \wedge \sigma_i \neq \text{undef} \end{aligned}$$

QED

Lemma 3

$$S[\$subgoals] = \text{try}[\$subgoals] = \sigma \wedge \sigma \neq \text{undef}$$

Proof:

Each subgoal is a function application $P(x_1, \dots, x_n)$ that is true if and only if the precondition on the input arguments is true and there exists a substitution σ such that $(x_1, \dots, x_n)\sigma$ is the unique output tuple associated with (x_1, \dots, x_n) by P . For the conjunction of a list of subgoals to be true, each must be true, and, since all their variables are bound by the same universal quantifier, a value supplied to a variable in the evaluation of one subgoal is propagated to all occurrences of that variable throughout the list of subgoals. Thus, $S[\$subgoals]$ is true if and only if there exists a substitution σ such that $\text{subgoal}_1\sigma \wedge \text{subgoal}_2\sigma \wedge \dots \wedge \text{subgoal}_n\sigma$.

All of this is implicit in the semantics of the intermediate form, simply a property of bound variables. The LISP form makes it all explicit by requiring that evaluation of $P(x_1, \dots, x_n) = \sigma$ where σ is the substitution such that $(x_1, \dots, x_n)\sigma$ is the unique tuple associated with (x_1, \dots, x_n) by P . If there does not exist any such substitution then try returns undef .

```

try[(\$subgoal1, ..., \$subgoaln)] =
  IF eval[\$subgoal1] =  $\sigma \wedge \sigma \neq \text{undef}$ 
     $\wedge \text{try}[\text{mk-subst}[(\$subgoal_2, \dots, \$subgoal_n), \sigma]] = \sigma'$ 
     $\wedge \sigma' \neq \text{undef}$ 
  THEN  $\sigma \circ \sigma'$ 
  ELSE undef

```

Note that since substitutions are made as you go, and evaluations that cause binding to variables always create new variables to bind to, we know that $\forall x$ such that σ contains a binding, say x/a , there does not exist in σ

any binding of the form x/y where $y \neq a$, or any binding of the form y/z where z contains x . Thus,

$$S[\$subgoals] = \text{try}[\$subgoals] = \sigma \wedge \sigma \neq \text{undef.}$$

QED

Sublemma 4.1

A recursive definition of the form:

$f[u] = \text{IF null}[u] \text{ THEN undef}$
 $\text{ELSE IF } P[\text{first}[u]] \text{ THEN } g[\text{first}[u]]$
 $\text{ELSE } f[\text{rest}[u]]$

has the property that, if $u = (u_1 u_2 \dots u_n)$, then

$$f[u] = a \wedge a \neq \text{undef} \quad \square$$

$$\exists! (g[u_i] = a \wedge a \neq \text{undef} \wedge P[u_i] \wedge (\bigwedge_{j=1}^{i-1} \neg P[u_j]))$$

This is a direct consequence of the definition of f , which specifies that each element of u is tested in the order given, and that no element is tested unless all before it in the list have been tried and have failed. We prove it by induction on the length of the list u .

Basis: $u = (u_1)$

$f[(u_1)] = \text{IF null}[(u_1)] \text{ THEN undef}$
 $\text{ELSE IF } P[u_1] \text{ THEN } g[u_1]$
 $\text{ELSE } f[]$
 $\square \text{ IF false THEN undef}$
 $\text{ELSE IF } P[u_1] \text{ THEN } g[u_1]$
 $\text{ELSE IF null}[] \text{ THEN undef}$
 $\text{ELSE } \dots$
 $\square \text{ IF } P[u_1] \text{ THEN } g[u_1]$
 ELSE undef

Thus, $f[(u_1)] = a \wedge a \neq \text{undef} \quad \square \quad P[u_1] \wedge g[u_1] = a \wedge a \neq \text{undef}$

Induction Step: Assume that for all lists of length $\leq n$:

$f[u] = a \wedge a \neq \text{undef} \quad \square$
 $\exists! (g[u_i] = a \wedge a \neq \text{undef} \wedge P[u_i] \wedge (\bigwedge_{j=1}^{i-1} \neg P[u_j]))$

$f[(u_1 \dots u_{(n+1)})] =$
 $\text{IF null}[(u_1 \dots u_{(n+1)})] \text{ THEN undef}$

ELSE IF P[u₁] THEN g[u₁]
 ELSE f[(u₂ ... u_(n+1))]

IF false THEN undef
 ELSE IF P[u₁] THEN g[u₁]
 ELSE f[(u₂ ... u_(n+1))]

IF P[u₁] THEN g[u₁]
 ELSE f[(u₂ ... u_(n+1))]

thus, f[(u₁ ... u_(n+1))] = a ∧ a ≠ undef

(P[u₁] ∧ g[u₁] = a ∧ a ≠ undef)
 ∨ (¬P[u₁] ∧ f[(u₂ ... u_(n+1))] = a ∧ a ≠ undef)

(i=1 ∧ g[u_i] = a ∧ a ≠ undef ∧ P[u_i] ∧ (∧ⁱ⁻¹_{j=1} ¬P[u_j]))
 ∨ (¬P[u₁] ∧ ∃i (g[u_i] = a ∧ a ≠ undef ∧ P[u_i] ∧ (∧ⁱ⁻¹_{j=1} ¬P[u_j])))

∃i (g[u_i] = a ∧ a ≠ undef ∧ P[u_i] ∧ (∧ⁱ⁻¹_{j=1} ¬P[u_j]))
 QED

Lemma 4

∃i (unify[Sid-list, Sarglist_i] = σ_i
 ∧ ∧ⁱ⁻¹_{j=1} (unify[Sid-list, Sarglist_j] = σ_j → ¬S[\$subgoals_j, σ_j])
 ∧ S[\$subgoals_i, σ_i])

bktrkcond[actuals, ((Sarglist₁ (cons 'try \$subgoals₁))
 (Sarglist₂ (cons 'try \$subgoals₂))
 ...
 (Sarglist_n (cons 'try \$subgoals_n)))] = σ
 ∧ σ ≠ undef

proof:

Let Salternatives = ((Sarglist₁ (cons 'try \$subgoals₁))
 (Sarglist₂ (cons 'try \$subgoals₂))
 ...
 (Sarglist_n (cons 'try \$subgoals_n)))
 then, bktrkcond[actuals, Salternatives] =
 IF null[Salternatives] THEN undef
 ELSE IF match[actuals, newversion[Sarglist₁]] = σ₁ ∧ σ₁ ≠ undef
 ∧ try[\$subgoals₁, σ₁] = σ₁' ∧ σ₁' ≠ undef
 THEN cleanup[σ₁, σ₁', actuals]
 ELSE bktrkcond[actuals, ((Sarglist₂ cons['try \$subgoals₂])
 ...
 (Sarglist_n cons['try \$subgoals_n]))]

thus, by Sublemma 4.1

$$\begin{aligned} & \text{bktrkcond}[\text{actuals}, ((\text{Sarglist}_1 (\text{cons 'try } \$\text{subgoals}_1)) \\ & \quad (\text{Sarglist}_2 (\text{cons 'try } \$\text{subgoals}_2)) \\ & \quad \dots \\ & \quad (\text{Sarglist}_n (\text{cons 'try } \$\text{subgoals}_n)))] = \sigma \\ & \wedge \sigma \neq \text{undef} \end{aligned}$$

■

$$\begin{aligned} \exists i \text{ match}[\text{actuals}, \text{newversion}[\text{Sarglist}_i]] &= \sigma_i \wedge \sigma_i \neq \text{undef} \\ &\wedge \text{try}[\text{subgoalist}_i, \sigma_i] = \sigma_i' \wedge \sigma_i' \neq \text{undef} \\ &\wedge \sigma = \text{cleanup}[\sigma_i, \sigma_i', \text{actuals}] \wedge \sigma \neq \text{undef} \\ \bigwedge_{j \neq i} \neg(\text{match}[\text{actuals}, \text{newversion}[\text{Sarglist}_j]] &= \sigma_j \\ &\wedge \sigma_j \neq \text{undef} \wedge (\text{try}[\text{subgoalist}_j, \sigma_j] = \sigma_j' \\ &\wedge \sigma_j' \neq \text{undef})) \end{aligned}$$

■

$$\begin{aligned} \exists i \text{ match}[\text{actuals}, \text{newversion}[\text{Sarglist}_i]] &= \sigma_i \wedge \sigma_i \neq \text{undef} \\ &\wedge \text{try}[\text{subgoalist}_i, \sigma_i] = \sigma_i' \wedge \sigma_i' \neq \text{undef} \\ &\wedge \sigma = \text{cleanup}[\sigma_i, \sigma_i', \text{actuals}] \wedge \sigma \neq \text{undef} \\ \bigwedge_{j \neq i} ((\text{match}[\text{actuals}, \text{newversion}[\text{Sarglist}_j]] &= \sigma_j \\ &\wedge \sigma_j \neq \text{undef}) \rightarrow \neg(\text{try}[\text{subgoalist}_j, \sigma_j] = \sigma_j' \\ &\wedge \sigma_j' \neq \text{undef})) \end{aligned}$$

by Lemma 2 we know

$$\begin{aligned} \text{unify}[\text{actuals}, \text{Sarglist}_i] &= \sigma_i \\ \text{match}[\text{actuals}, \text{newversion}[\text{Sarglist}_i]] &= \sigma_i \wedge \sigma_i \neq \text{undef} \end{aligned}$$

by Lemma 3, we have

$$S[\text{subgoals}] = \text{try}[\text{subgoals}] = \sigma \wedge \sigma \neq \text{undef}$$

thus, we have

$$\begin{aligned} \exists i (\text{unify}[\text{Sid-list}, \text{Sarglist}_i] &= \sigma_i \\ &\wedge \bigwedge_{j \neq i} (\text{unify}[\text{Sid-list}, \text{Sarglist}_j] = \sigma_j \rightarrow \neg S[\text{subgoals}_j, \sigma_j]) \\ &\wedge \wedge(\text{subgoalist}_i, \sigma_i) \end{aligned}$$

■

$$\begin{aligned} & \text{bktrkcond}[\text{actuals}, ((\text{Sarglist}_1 (\text{cons 'try } \$\text{subgoals}_1)) \\ & \quad (\text{Sarglist}_2 (\text{cons 'try } \$\text{subgoals}_2)) \\ & \quad \dots \\ & \quad (\text{Sarglist}_n (\text{cons 'try } \$\text{subgoals}_n)))] = \sigma \\ & \wedge \sigma \neq \text{undef} \end{aligned}$$

QED

THEOREM (Correctness of LISP form)

$$\forall \bar{x} \text{ defined}[\text{inputs}[\text{Sid-list}, \text{Input-pattern}]] \wedge \$\text{precondition} \rightarrow$$

$$\begin{aligned}
& [\exists i (\text{unify}[\$id\text{-list}, \$arglist_i] = \sigma_i \\
& \quad \wedge \bigwedge_{j=1}^i (\text{unify}[\$id\text{-list}, \$arglist_j] = \sigma_j \rightarrow \neg S[\$subgoals_j, \sigma_j]) \\
& \quad \wedge S[\$subgoals_i, \sigma_i]) \\
& \quad \rightarrow (\$id\text{-list})\sigma_i \in \$name)] \\
& \wedge \\
& \forall \bar{x} [(\$id\text{-list} \in \$name) \rightarrow \$postcondition] \\
& \quad \square \\
& \forall \bar{x} [\text{true-precond}[(\text{cons } \$name \text{ actuals})] \\
& \quad \wedge \text{bktrkcond}[\text{actuals}, ((\$arglist_1 (\text{cons 'try } \$subgoals_1)) \\
& \quad \quad (\$arglist_2 (\text{cons 'try } \$subgoals_2)) \\
& \quad \quad \dots \\
& \quad \quad (\$arglist_n (\text{cons 'try } \$subgoals_n)))] = \sigma \\
& \quad \wedge \sigma \neq \text{undef} \\
& \quad \rightarrow (\text{actuals})\sigma \in \$name] \\
& \wedge \forall \bar{x} [(\text{actuals} \in \$name) \rightarrow \$postcondition]
\end{aligned}$$

Proof:

The proof has actually all been accomplished through the lemmas. We take it as obvious that the second conjunct of the first expression is equivalent to the second conjunct of the second expression. Lemmas 1 and 4 supply the necessary parts to put together the equivalence of the first conjuncts of each expression.

Adding a New Target Language

In this section we describe how to add a new target language to the system. The first and most important step is to choose an implementation strategy.

One has a great deal of flexibility at this point. A balance must be found between compatibility with the full power of the specification language and with programs written directly in the target language. The main objective is to generate correct programs in the target language - not to extend or re-define the capabilities of that language. We would like the programs written from their specifications to be able to interact in well-defined and convenient ways with programs written directly in the target language.

If the target language distinguishes functions from procedures, then it may be preferable to use procedures as the implementation of all functions. In this way the

variable bindings are simply a side effect of the computation, which is the way it happens in logic anyway. If one wanted to stay close to logic, all functions would be implemented as boolean functions. Once a strategy has been decided upon the following functions/procedures should be implemented. All of these definitions are to reside in the target language system except for *make_(language name)_def* and *autopred*. These two functions are meant to be added to the program generation system. The only change to be made in the system is in the function *translate*. For type-free languages, the clause *((eq target 'language) (make_language_def))* is added; for typed languages, the clause *((eq target 'language) (mk-strong-typed) (make_language_def))* is added.

1. Primitives:

The functions and predicates listed here are labeled "primitives" because we assume they need not be further defined. The set of primitives given here is neither minimal nor exhaustive, just convenient. One's target language may supply more than these, or less.

If one supplies more primitive types for a strong-typed language, then the system must be informed of those type names. This may be accomplished by type specifications with empty bodies, i.e. when asked for the body part of the specification, simply type a period. Note that this is only for type definitions, and only for strongly-typed languages. For type-free target-languages, and for all other function definitions, if one wishes to make use of a function or predicate already defined in the target language, then one should use the "*zf*" or "*zp*" facility (see page 82).

If a target language is unable to supply some of the following primitives, one may still use the system, but should not make use of those undefined primitives in any specifications.

- a. **Predicates** - primitive predicates do not have an output variable. They are defined in the target language such that they always take true or false as value, in type-free languages, and, if the language is typed then they must either be primitive or defined types in that language. Occurrences of these type predicates in preconditions and postconditions will simply become declarations in a typed target-language.

Integer(x)
Real(x)
Boolean(x)
Is-String(x)
Is-List(x)

binary relational predicates: =, ≠, >, <, ≥, ≤

(I/O): Firstsym(x y z) - meaning y is the first symbol, i.e.token, of x, leaving z.¹⁴

Firstexp(x y z) - meaning y is the first expression on x, leaving z, where

expression ::= constant | variable | "(" expression* ")"

Write(x) - has the value true for all x, and has the side effect of printing the value of x on the current output device.

- b. **Functions** - these are functions whose application to arguments result in terms. Thus, they do not carry output variables. The predicate-ized version of any of these (see page 82) is obtained by preceding the name with "%f"

(Integer): +, -, *, /, rem

(Real): r+, r-, r*, r/

(Boolean): ∧, ∨, ¬

(String): string(l)-makes a string out of a list of characters

s-cat(s1 s2) - string concatenation

s-cons(c s) - adds a character to the front of a string

¹⁴The specification of the system is done in such a way that *Firstsym*(x, y, z) could simply be implemented as a scanner which gets the first token of input, binds it to y, and ignores x and z. *Firstsym* with three arguments indicates unlimited backtracking abilities over input. Since this is not always implementable in one's target language, one must use the general form judiciously. Similarly with *Firstexp*.

firstch(s) - gets the first character of a string
 tail(s) - rest of a string (without first character)
 mk-string(c) - makes a string of a single character
 (List): first(l) - gets first element of a list l
 rest(l) - gets the list l without the first element
 cons(x l) - adds x to front of list l
 list(x1 ... xn) - creates a list with elements x1 ... xn

- c. Constants - the grammar for the intermediate form describes the constants of the system, and of course any mapping to another language must be able to recognize constants. The reason we mention them here specifically, is that we have included at least one constant that is not universally available in typical programming languages. This constant is of course *undef*. It may not be convenient (or even possible) to introduce such a constant in strongly typed languages. However, the purpose of *undef*, i.e., some way of indicating that we have determined that a well-defined value in the appropriate domain does not exist, should be implemented. More is said about this in the section on implementing strongly-typed languages.

2. The following functions must also be implemented. The first, *make_(language name)_def*, should be an actual function or procedure name. The others are indicative of what needs to be accomplished. They need not exist as explicitly defined functions. For example, the target language does not need to have a procedure named *bktrkcond*, however, the function of *bktrkcond*, i.e., the selection of alternatives to attempt in order to complete a computation, must be accomplished by some means.

- a. *make_(language name)_def* - This function has available all the information of the intermediate language definition. It creates the target language definition, i.e., the actual syntax of a procedure declaration/definition in the target language.
- b. *bktrkcond* - This function may be accomplished as an ordinary conditional, allowing several options, or as a sequence of IF-THEN-ELSE's with added conditions to ensure completion of only one alternative.

- 1) *undef* - A distinguishable bottom element of every type is used as an undefined element. Languages that are strong-typed without the ability to add a single element to an existing type cause trouble here. In these cases, a variable *undef* may be used which is local to each *bktrkcond* and passed through to *try*.

- c. *match* - The pattern match may simply be a unification algorithm; a more general matcher will allow more complicated input to the matcher, and thus enhance the system's efficiency if done well. A simple unification algorithm is guaranteed to be correct, but requires that one must only desire syntactic matching. That is, the matcher would not be able handle the unification of any data types that have more than one representation.
- d. *try* - The function *try* attempts to complete the computation of a list of procedure calls. If any call is unsuccessful, then *try* fails, and another alternative is selected by *bktrkcond*.
- e. a precondition checker - This may be implemented as a type check and/or first condition of the procedure body, governing the execution of the rest of the body.

Each of the functions mentioned above may require several subfunctions. For example, in a typed language one would probably split *make_(language name)_def* into sub-parts such as *make_dec_part* and *make_body_part*. One also needs to check whether the lexicon of the intermediate language is compatible with the lexicon of the target language, and provide a mapping from one to the other if they are not. Of particular concern here is the fact that the *autopred* facility allows identifiers whose first characters are the symbol *%* and the internalized form of the formal parameters are identifiers with first symbol *!*.

3. Define *autopred* to allow use of language-system-defined functions and procedures (see page 82). Also helps in the automatic predicatizing of the primitive "functions" mentioned in step 1.

10.1 Implementation Strategy for LISP

The definitions of the primitives for LISP are given in Section 16.1, beginning on page 156. The choice of an implementation strategy was changed after seeing the results in the first implementation of LISP. We discuss this here since the lesson learned in the process may be applicable to several languages.

Every function call in most implementations of LISP returns a single value.¹⁵ Thus, in the original implementation it was thought that to be consistent with LISP every function call should return the value of its output variable. This decision seemed quite natural at first, in fact it seemed the only way to be compatible with ordinary LISP.

No problems arose as long as the functions being defined had precisely one output variable. It somehow seemed reasonable to expect that one should only want to compute a single value when dealing with a language in which that is the norm. However, when faced with a function having two or more output variables, one had to choose which was to be the value returned. The arbitrary choice was made that the first output variable would carry the value returned by the function call. Although somewhat dissatisfying this choice caused no major problems, immediately.

The point at which the strategy was found to be inadequate came when implementing the propagation of the values of the output variables to the rest of the current list of subgoals. It was certainly possible to do this, but it was not pretty.

A new strategy was chosen. Each function call would return a substitution. This strategy is completely compatible with LISP in that a substitution is indeed a single value. It was still easy to automatically generate "predicate-ized" versions of LISP-system functions.

The new implementation turned out to be much cleaner and more amenable to

¹⁵See *Anatomy of LISP* [A 78] for a discussion of an implementation of LISP with multiple-valued functions.

proof than the old. The lesson to be learned from this is that there are usually many possible choices of implementation strategy, one should not feel stuck with the first choice, and one should not overly restrict the implementation by avoiding what may at face value appear to be an extension of the target language, but in fact is not.

10.2 Implementation of Pascal

In any typed language, some additional information about the types of parameters and local variables is desired, and it is convenient to generate this information once and keep it where one can continually reference it. When it is recognized that a program is to be generated in a strongly typed language we add more information to the property list of the function being defined.

A list of the formal parameters and their types is put under the property *types*. These types are gleaned from the precondition and postcondition specifications. The remainders of the precondition and postcondition (i.e. that which is in addition to type specifications) are listed on the *typedprecond* and *typedpostcond* properties of the function.

The body of the function is searched to determine the names of all functions that are called by the function being defined, and this list of names is stored under the *external-procs* property. A list of the local variables and their types is generated and stored under the *local-decs* property. When an external declaration is made for a

function, it is also kept so that the same declaration need not be derived again for every other function that calls it.

In Pascal, a function or type specification is implemented as a boolean function with value parameters corresponding to the input parameters and *var* parameters corresponding to the output parameters. A function will return the value *true* if it is successful and *false* if it is not. All user-defined types are treated as one type, and functions are generated to distinguish among them.

If one wishes to translate to Pascal, or any strongly typed language, part of the precondition must be a type specification for each input parameter, and part of the postcondition must be a type specification for each output parameter. This means that there may be some specifications that are legal input to the system that will not be translatable into Pascal.

The necessary additions to the system for implementing Pascal as a target language may be found in Section 16.2, page 172. Appendix A, which contains several sample specifications and their translations into LISP programs, exhibits only one generated Pascal program. This is due to the extreme ugliness of the implementation of the "back end" for Pascal. To satisfy the type restrictions of Pascal we had to either disallow user-defined types or map all types to a general type (we used "term"). Mapping all types to one results in a very general structure. This structure is nice theoretically in its universality, but unwieldy in practice. We felt the point could be shown by exhibiting the translation of the factorial function. The full generality of the structure is used even for this simple example, and we are unable to

simplify it for the cases in which we are only dealing with the base types of Pascal.

The primitive functions and predicates are defined to take advantage of the operations possible on base types; however, this is because the primitives are implemented by hand and can be designed individually.

In conclusion, the implementation of Pascal has shown that strongly-typed languages may be added to the system; however, if the system is to be considered for "practical" use, an implementation that encodes types more efficiently should be investigated.

Implementation Notes

The top level of the system is called "top" and is called by typing "(top)" to MACLSP. When the program is initialized it prompts the user suggesting that if help is needed one should type "?". This results in instructions for input specifications. The system prompts the user for individual parts of a specification, and again a "?" response will provide information about the required specification, along with an example.

When the user terminates a session, by typing "." at the top level, the system asks if one wishes to save the definitions of the session on a file, and asks for a filename if the answer is affirmative. Before terminating the session, the system informs the user how to include the definitions just saved the next time the system is started.

The pattern-matcher plays an important part in the computation of programs.

Alternatives in the backtracking-conditional are chosen by matching the actual parameter list against a pattern. A straight unification algorithm is easy to implement but not always as powerful as we would like. It works well where there is a unique representation of the objects we are trying to match. If one chooses to define a data type in which the representation for each element is not unique, then one should also define an equality predicate "*Equal- \langle type \rangle* " for the type, and if one desires more than syntactic matching to occur, a function "*Equal-bind- \langle type \rangle* " that will attempt to match two elements of the type. All other equality testing and matching is done syntactically.

For example, if one chose to represent sets as unordered constructions rather than imposing some order, one might provide the following specifications:

```

type Set
body? Set(Mt-set, true)
      Set( Add-elm(y,X), true)  $\leftarrow$  Set(X, true), Member(y, X, false).

function Equal-set
input-pattern? (1 1 0)
parameter-list? (x y z)
precondition? Set(x, true)  $\wedge$  Set(y, true).
postcondition? Boolean(z, true).
body?
Equal-set(x, y, true)  $\leftarrow$  Subset(x, y, true), Subset(y, x, true).

```

Of course, "*Subset*" and "*Member*" must also be defined.

Note the use of *false* in the second clause of the specification of the body of *Set*. Negation of predicates is not allowed by the syntax of Horn clauses; using a truth-valued output variable we are able to incorporate negative tests into the language. In the definition of *Member* we would have a clause: *Member*(x, (), *false*) \leftarrow

The *true* or *false* used as an argument of a predicate must be considered a constant (or 0-ary function symbol) not a predicate. When using the constant predicate, *TRUE* or *T*, we distinguish it here by capitalization. The user should be aware of the distinction, however, it is not necessary to communicate it to the system through capitalization since the distinction can be determined by context.

Failure to find an answer will cause the value *undef* to be returned. This is an indication that the answer is undefined either because we attempted to apply a predicate to arguments not in its domain (as specified by the precondition) or we failed to match on all of the clauses of the definition. Returning *undef* will fail the subgoal it is returned to and thus fail the current clause and the next alternative will be attempted. At this level, *undef* is denoting failure to successfully terminate a computation.

At another level, *undef* is a constant that is assumed to be in every domain. It is possible that one might call a subgoal with the constant *undef* in an output variable position; in this case, if *undef* is the value that would be bound to that position, then the subgoal will succeed. There are times when *undef* is the appropriate answer to be returned from a function. For example, if one defines a look-up function that takes a name and a list of name-value pairs, and returns the value associated with the name, then one would expect an output value *undef* if the name does not occur in the list.

The system will provide default values for the parameter-list, precondition, and postcondition of the specification of a function as it does for a type specification. This

makes the input of specifications easier but is not recommended for general use. Even when specifying a program that is only expected to be partially correct, one should be able to provide a precondition that would at least keep some bad inputs from being accepted.

A further convenience for the user, the system will automatically "predicate-ize" functions that are pre-defined in the target-language system. The user indicates such functions to the synthesis system by prefixing the name of a function with "*zf*" and the name of a system predicate (boolean valued function) with "*zp*". An output variable is added to the argument list and the new predicate may be used as any other. For example, the recursive clause for the definition of factorial:

$$fact(x, y) \leftarrow zf_{subl}(x, x1), fact(x1, y1), zf_{*}(x, y1, y)$$

makes use of the system functions "*subl*" and "***". Again, since these are being defined automatically, the preconditions are simply "true", so the only type checking done will be that provided by the target language. We do not guarantee correctness for definitions made in terms of system functions.

The mapping to a strongly-typed language requires that more detail be spelled out. When the system recognizes that the target language requires explicit declaration of types, it derives from the specifications some additional properties that will be useful in the translation. These include a list of formal parameters associated with their types, a list of local variables and their types, and a list of all functions that are called by the one being specified.

Conclusions and Further Research

We have shown, through proofs of the correctness of the mappings involved, that the system described in this document provides a valid way of generating correct programs. The system works by adding control information to the logic that is specified by the user. The user is still left with the task of inventing the computational logic description of the program desired. We feel that this is reasonable and an advance in the process of obtaining a correct program since the programmer is no longer burdened with the problem of describing the flow of control of the program.

The system as described is "reasonably" target-language-independent. We qualify this statement only because it is easier to translate to some languages than to others. For ease of translation, the target language should allow recursion. The

"back-end" necessary to translate to a non-recursive language, although certainly feasible, would be more complicated than that for a language allowing recursion due to the necessity of translating recursive algorithms. We feel this is almost no restriction at all since we believe that recursion is important enough to be a minimum requirement for any language to be considered "reasonable".

The type structure of a target language is an important factor in determining the ease of its addition to the system. The simplest languages to deal with are those that are type-free, allowing type specifications to be translated into functions that are recognizers for the type being defined. In a typed language, one often feels the need (or desire) for polymorphic functions as allowed by LCF. LCF checks the consistency of types without insisting on knowing precisely the type of every object at compile time. For example, one can define the function *compose*, which takes two arguments of functional types and returns a value of functional type. The type assigned to *compose* by LCF is: $((\text{type2} \rightarrow \text{type3}) \times [\text{type1} \rightarrow \text{type2}]) \rightarrow [\text{type1} \rightarrow \text{type3}]$. A simple example of another function that is by nature polymorphic is a symbol table lookup. The type of the result of a lookup should agree with the type of the variable the function is called with. However, there may be several different types of variables and values in the table at any time.

The use of generic functions in the specifications is a new feature making it possible to synthesize several programs from a single specification. Generic functions also provide a convenient tool in defining other functions. The portability of the

system is evidenced by its ability to generate a version of itself.¹⁶ Thus it is easily bootstrapped given the "back-end" for the language desired. The ability to generate itself is also an indication that the system can handle large "practical" problems. Several sample programs have been generated, many are listed in Appendix A.

Several extensions to the system and subjects of further research have suggested themselves along the way. We divide these loosely according to whether they deal with the front-end of the system, the present capabilities of the system, or the back-end required to add a new language.

We would like to add a front-end to the system that would allow more natural input. This includes several extensions of the syntax of the specification language. First, the use of embedded function applications cuts down on the amount of typing necessary. We can trivially make use of function applications that have only a single output variable by a simple syntactic manipulation that replaces the occurrence of these in argument positions by a temporary variable and adds the function application, with that same variable in the output position, to the subgoals of the clause in which it occurs before sending the input to the system. If we are also to

¹⁶The version of the system which was generated from the specification given in Chapter 15 is slow in comparison to the hand-written version. We believe this is largely due to the simple-minded pattern matcher being used, which makes actual substitutions rather than simulating them with binding of variables. This is actually a problem with the implementation of *match* written directly in LISP rather than a problem with the specification.

include functions that have not yet been defined, then we must have a way of distinguishing them from constructor functions ¹⁷, which must never be turned into predicates. This is not difficult and can be done in any of a number of ways.

Secondly, we can extend the syntax of Horn clauses to allow mixed conjunctions and disjunctions of positive literals (still no negation allowed) on the right hand side of the " \leftarrow ".

Thirdly, it would be nice to allow full use of Predicate Calculus in the specification of a function. This is a much more difficult problem. Synthesis of programs from general descriptions is being studied by several researchers ([C 77], [CD 78], [CS 77], [D 75], [D 77], [DM 75], [MW 77a], [MW 77c]). Hopefully, their results may be incorporated in this system in the future. Brian Beach, a student at the University of California, Santa Cruz, has implemented an interactive system that helps one derive Horn clauses from more general statements in Predicate Calculus [B 79].

Lastly, we would like to include an interactive program that helps the user derive the specifications for a program and prove the correctness of the specifications. The system could check the completeness of the specification by making sure that at least one Horn clause is applicable to every element of the domain of the function as specified by the precondition. This is difficult in general but for inductively defined domains may simply be a reminder to the programmer that they include basis and

¹⁷Constructor functions are used to define data structures inductively. For example, the definition of type *Set* given on page 21 uses the constructor function *Add-elm*.

constructed elements. To prove the correctness of a specification one must: 1) Prove each Horn clause as a theorem in the problem domain; 2) Prove that the precondition guarantees termination of the program (usually a proof by induction on the input); and 3) Prove that successful termination of the program always results in an answer satisfying the postcondition, and that the answer produced is unique. This is then a proof that we have a correct specification of a problem; again, we can never prove it is the problem we had "in mind". It is of course too much to expect that the system be capable of doing all of this on its own, but a semi-automatic verifier or proof checker would be useful.

There are also several extensions to the capabilities of the system that are desirable. We would like to extend the use of generic function specifications to allow selection of individual versions of the function by type of the arguments as well as by input pattern. Another useful feature would be obtained by making arrays a primitive data type. Array access is not achieved efficiently by a logic program; since most available languages offer arrays as a primitive type, we could make use of them in specifications realizing that the fast index algorithms of a target language would eventually be used by the program.

Functional arguments are disallowed in any first-order theory, however, we could circumvent the jump to second order and its associated problems by considering the use of function names as arguments. These names could then indicate where we might find the appropriate definition of the function we wish to use.

Another restriction we have imposed is the functionality of our specifications.

This gave a great savings in terms of the limited backtracking needed for evaluation (over clauses, but never over subgoals). We would like to include a way of indicating that selective subgoal backtracking is desired. This would give us the ability to make statements about the existence of an answer that satisfies several subgoals simultaneously. Each subgoal may be satisfied by a set of answers, we want an element of the intersection of these sets.

There are several ways of improving the efficiency of the generated programs. We intend to incorporate some analysis to determine the best ordering of alternatives and of subgoals within alternatives. We would also like to generate programs to optimize the source language programs for particular target languages. In languages in which recursion is implemented inefficiently, this would include removal of recursion.

The most dramatic improvement to the system would be the development of a program that could automatically generate the mapping from intermediate to target language from a formal specification of the syntax and semantics of the target language. This is similar to the work being done on translator writing systems, the difference being that the target is a high level programming language rather than a machine language.

Appendix B: Specification of a Program Synthesis System

Note that *env* is used to denote a global environment containing information necessary to several of the following functions. The structure of *env* is a list of three elements: 1) a list of all generic function names along with their selection lists; 2) a list of the names of all functions defined so far; and 3) a list of all types defined so far. The environment, *env*, is initialized to a list consisting of three empty lists.

16.2 Listing of Pascal Implementation

;lisp programs for generating pascal
 ;each function specification gets turned into a complete program so that
 ;a library of functions can be built. Each function is declared external.
 ;the surrounding program is just a dummy to satisfy syntax restrictions.

;a type specification is turned into a type declaration and stuffed on the
 ;property list of the type name (under 'type-dec), to be
 ;included in the declaration of every
 ;function that uses the type. (apparently there is no such thing as an
 ;external type in pascal, so it has to be re-declared everywhere)

```

(def make_pascal_def ()

;local-vars and donelist are global to several of the above functions. They are the means by which information about which terms have been generated and must be declared are transmitted about. Local-vars is a list of 4 lists of variables that must be declared as termlists, terms, constants, and symbols, respectively. Every time a new variable is created it is added to this list in the appropriate type sublist. Whenever a variable (pointer) is created that may appear again, it is added to donelist so that multiple versions need not be generated.

The following programs were written directly in Pascal as part of the implementation of the "back end" for the language.

(*pascal programs*)

(*\$E+*)

program Junk,Unify,Subst,Replace,Copytermlist,Copyterm,Copyconst,Copysym;

(*pascal can't handle things the way it should so we have to invent strange names that are all referring to the same thing, in particular, the type of the object at hand. Thus, alltypes, an indication of the possible atomic types, is actually made up of convoluted versions of the type names. this idiocy is carried on throughout, which is why you'll see several different names that all look similar but had to be different for pascal. *)
